Executive Summary

Alberta is currently in the process of updating its Climate Change Action Plan. As part of this process, Alberta is interested in understanding the potential for greenhouse gas reductions throughout the economy. The primary objective of this report is to estimate the likely greenhouse gas reductions that would be available from several alternative greenhouse gas policies using a technologically detailed energy-economy model. In addition, the analysis in the report forecasts the economic impacts of those policies. This report is an initial exploration of greenhouse gas policies in Alberta. It is not an exhaustive exploration of policy alternatives, and does not prescribe a policy package that Alberta should implement.

We quantitatively estimated the response of the Alberta economy to two general types of greenhouse gas policy:

- **Carbon charges**, which require emitters of greenhouse gases to pay a fixed charge proportional to their emissions. This type of policy sends a marginal cost signal to all emitters throughout the economy and should result in economically efficient greenhouse gas emissions reductions throughout the economy. The analysis of carbon charges also provides information on the strength of policy required to reach a target for greenhouse gas emissions.
- **Regulations**, which require the use of certain types of technologies or processes in a given sector of the economy.

To determine the effect of each type of policy, we first developed a reference case to show the likely trajectory of greenhouse gas emissions in Alberta in the absence of climate change policies.

Reference case forecast

- **Alberta's emissions are likely to continue to increase rapidly in the absence of new climate change policies.** Our forecast is based on external assumptions about population growth, economic growth, fuel prices, and fossil fuel production, coupled with analysis of technological development and adoption over time. We project that Alberta's emissions will grow by roughly 50 percent from current levels by 2020 and by roughly 80 percent from current levels by 2050 in the absence of new climate change policies. The primary reasons for the growth in emissions are rapid expansion of production in the upstream oil sector (production is forecast to increase about fourfold by 2050), growth in the energy transformation sectors (primarily petroleum refining and electricity generation), and growth in the transportation sector.

Results of carbon charge modelling

- **Because Alberta is likely to undergo such fast growth in emissions in the reference case, reducing absolute emissions below 1990 levels is likely to be challenging. Even stabilizing emissions at current levels will require**

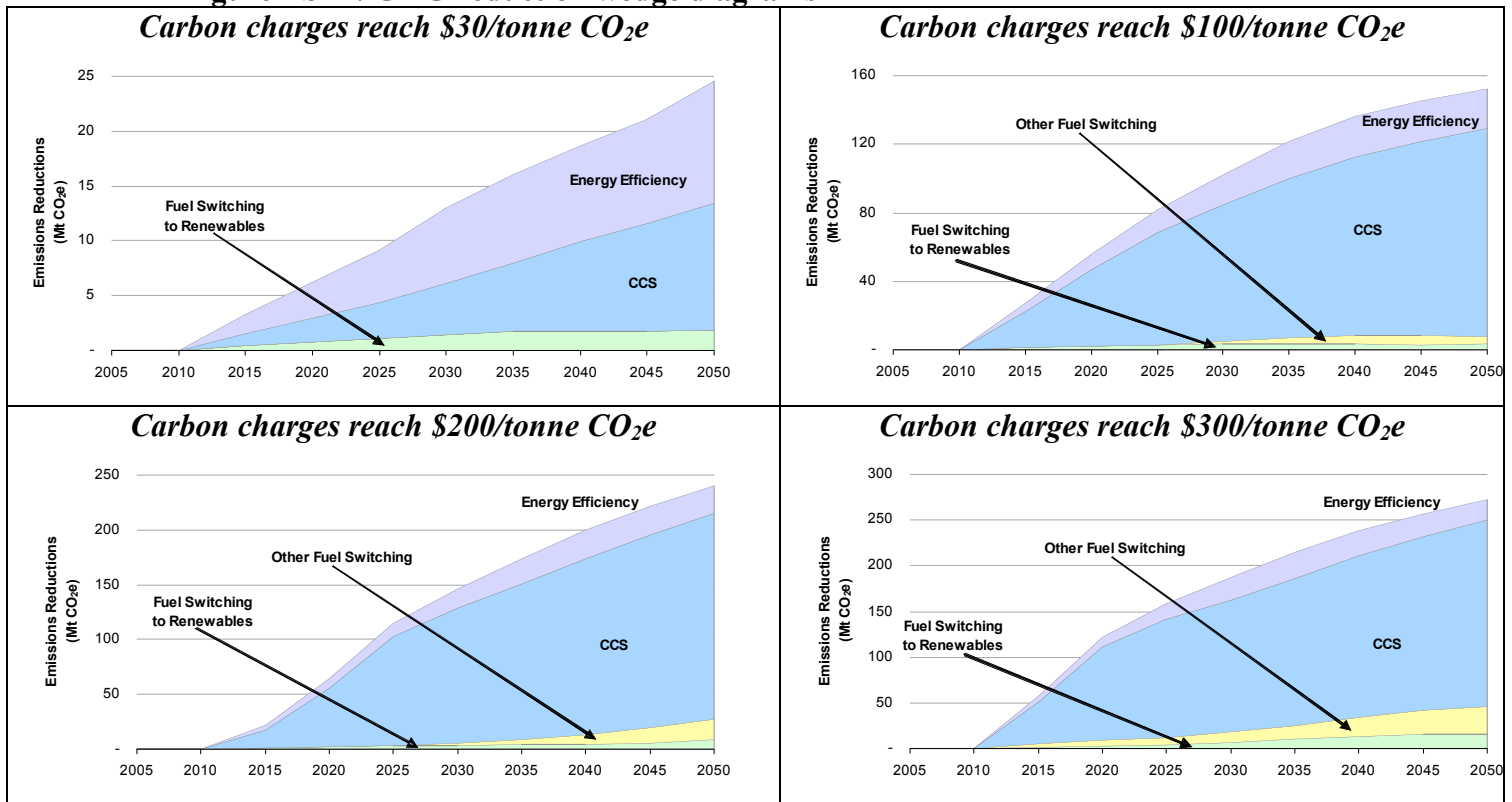

significant policy intervention. Figure ES-1 shows projected GHG emissions in the reference case as well as in several of the policy scenarios that were modelled for this report. All of the policies are *carbon charges*, which require emitters of greenhouse gases to pay a fixed charge proportional to their emissions. The figure shows that modest greenhouse gas policies (for example, where the carbon charge is \$30/t CO₂e) still allow significant growth in emissions from today's levels. Stronger policies (where the carbon charge reaches \$100/t CO₂e by 2050) can reduce emissions to around today's level by 2050. The policy where the carbon charge reaches \$200/t CO₂e by 2050 reduces emissions to 1990 levels by 2050; and when the carbon charges reaches \$300/tonne CO₂e, emissions decline by around 45% below 2005 levels by 2050.

Figure ES-1: GHG emissions in policy scenarios, excluding emissions from agroecosystems and waste

- **For large greenhouse gas reductions, carbon capture and storage is the key GHG-reduction action. Energy efficiency and fuel switching actions play a smaller role in reducing GHG emissions.** Figure ES- 2 breaks the emissions reductions associated with each of the policies that were modelled into *wedges*. It shows that when GHG policies are modest (e.g., when the carbon charge is \$30/t CO₂e), energy efficiency, fuel switching, and carbon capture and storage all contribute to overall emission reductions. At higher carbon charges, carbon capture and storage becomes more economic and contributes the largest share of overall emission reductions. The analysis suggests that for large, cost-effective GHG reductions, carbon capture and storage will be critical.

Figure ES- 2: GHG reduction wedge diagrams

- **Most cost-effective greenhouse gas reductions will occur in the upstream oil and gas and electricity generation sectors.** These sectors are projected to produce the most GHG emissions in the reference case, and also to offer potential for cost-effective GHG reductions. The upstream oil and gas and electricity generation sectors are the most likely candidates for cost-effective carbon capture and storage, which is likely to become economical at higher carbon charges.
- **Significant greenhouse gas reductions will likely cause household and vehicle energy bills to increase.** The likely impact of a carbon charge on household and vehicle energy bills ranges from modest increases in the least aggressive scenarios to more significant increases (40 percent and above) in the more aggressive scenarios. In each scenario, household energy bills increase most substantially when the policy is first implemented. However, as households respond to the policy by adopting more energy efficient technologies or switching to low emissions fuels, energy bills begin to decline. For the policy where carbon charges reach \$100/tonne CO₂e, the analysis projects that household energy bills could increase initially by as much as 40 percent above the reference case. For the modest policy, household energy bills would increase much less (approximately 5 percent). As households adjust to the policy, the difference between the reference case and the policy declines substantially. At the end of the simulation, energy bills in the policy where carbon charges reach \$200/tonne CO₂e are only 2 percent greater than in the reference case. For the more aggressive policies, the modelling also projects significant increases in gasoline

price, which corresponds to increases of about 50 percent in annual vehicle fuel costs in the policy where carbon charges reach \$200/tonne CO₂e. Again, the more modest policies simulated show much less effect on annual vehicle costs. Like household energy costs, the annual vehicle fuel costs would converge with the reference case over time, as the policy induced energy efficiency improvements in the vehicle stock. A policy that begins modestly and predictably increases in aggressiveness over time would help to mitigate economic impacts.

- **A broad market-based policy is unlikely to significantly reduce Alberta's economic growth.** The model used for this analysis is not a full economic equilibrium model and so cannot project impacts of the policy on the entire economy. However, the model suggests that even an aggressive carbon charge is unlikely to dramatically affect overall economic output in the portion of the economy covered by the model. With aggressive GHG policy, a structural shift in Alberta's energy sector from crude oil production towards electricity generation is possible. The economic effects of the policy will depend on the details of the policy that is applied (for example, how revenue raised from the policy is recycled throughout the economy).

Results of regulatory policy modelling

In addition to modelling the likely impact of broad carbon charges applied throughout the economy, we also estimated the likely impact of several specific regulatory policies on greenhouse gas emissions. The policies modelled here do not represent an exhaustive list of potential regulatory policies that could be applied in Alberta, and may not represent options being considered for implementation in Alberta. Based on the modelling, we found the following results:

- **A residential building code requiring Built Green™ Gold for new construction after 2010 would reduce Alberta's greenhouse gas emissions by about 0.3 Mt in 2025 and about 0.6 Mt in 2050, compared to the reference case.** The relatively modest overall impact of this regulation is due to the fact that Alberta's residential sector accounts for a very small fraction of total emissions and that energy efficiency is forecast to improve fairly quickly in the residential sector in the reference case.
- **A commercial building code requiring new construction to meet LEED Gold™ standards would reduce Alberta's emissions by 1 Mt in 2025 and about 5 Mt in 2050, compared to the reference case.** Similar to the regulation on residential buildings, the impact of this standard is modest because the commercial sector accounts for a small portion of Alberta's total emissions. However, the standard induces significant improvements in the energy efficiency and greenhouse gas intensity of commercial buildings.
- **A vehicle emissions standard that requires the average greenhouse gas intensity of vehicles sold in Alberta to match regulations in California would reduce emissions by 2 Mt in 2025 and 2 Mt in 2050.** The standard would induce an 18% improvement in the greenhouse gas intensity of the passenger

- vehicle stock in 2025. The impact of this policy is modest because its scope is limited to passenger vehicles in the transportation sector, while freight transportation and air travel are unaffected. The emissions reductions from the standard do not increase between 2025 and 2050, because the emissions intensity of passenger vehicles improves in the reference scenario while the policy stays constant.
- **Construction of a 2,200 MW nuclear plant in 2020 would reduce Alberta's emissions by about 11 Mt in 2050, compared to the reference case.** Because nuclear generated electricity produces no greenhouse gas emissions, construction of a nuclear plant would offset some of the demand for electricity generation from fossil fuel, and reduce GHG emissions.
 - **A requirement for 20% of electric generation to be from renewable sources by 2020 would reduce emissions by about 5 Mt in 2025 and by about 6 Mt in 2050.** A greater generation from renewable energy sources offsets the demand for generation from fossil fuels.
 - **A regulation requiring all large industrial facilities built after 2015 to capture and store greenhouse gases wherever possible would reduce emissions by about 61 Mt in 2025 and by 173 Mt in 2050.** A large fraction of Alberta's GHG emissions are from large industrial facilities, and this fraction will likely increase with continued growth in the oil industry. A stringent regulation requiring widespread capture and storage of GHG emissions would dramatically reduce overall emissions in Alberta. We also modelled a scenario where the carbon capture and storage policy was combined with a broad carbon charge covering the entire economy. We found that greenhouse gases would be reduced by about 70 Mt in 2025 and over 200 Mt in 2050 using this combination of policies.
 - **A policy package that includes most of the regulatory policies discussed above would reduce emissions by about 68 Mt in 2025 and by about 181 Mt in 2050.** The policy package includes all the regulatory policies except the requirement for 20% of electric generation to be from renewable sources. The package does not include a carbon charge.

Figure ES- 3 shows the impact of the regulatory policies modelled compared to the reference case. The emissions trajectory for some of the policies is not illustrated because the impacts are modest.

FINAL REPORT

Figure ES- 3: GHG emissions in regulation scenarios, excluding emissions from agroecosystems and waste

Introduction

Context

Alberta published its first Climate Change Action Plan in 2002. This plan set a target of reducing provincial greenhouse gas intensity (tonnes of greenhouse gases per dollar of gross provincial product) by 20 percent between 1990 and 2010, and by 50 percent by 2020.¹ In order to meet these targets, the Alberta government introduced several policies, with the most important being the *Climate Change and Emissions Management Act*. Under this legislation, large industrial facilities are required to reduce greenhouse gas intensity by 12 percent compared to their 2003 – 2005 baseline, starting in 2007. Supporting policies, including a domestic offset system and a technology investment fund, are also in the process of being developed.

Figure 1 shows Alberta’s historic greenhouse gas intensity since 1990 as well as a forecast of emissions intensity through 2020. The figure suggests that Alberta is on track to meet its 2010 target with current policies, but that additional policies may be required to enable Alberta to reach its 2020 emissions intensity target.

Figure 1: Alberta historic and forecast reference case GHG intensity

Source: Historic data from Environment Canada, 2007, “Canada’s Greenhouse Gas Inventory”. Forecast data from Natural Resources Canada, 2006, “Canada’s Energy Outlook: The Reference Case 2006”. We use the NRCan forecast for this figure because it includes emissions from agroecosystems and waste, which are included in Alberta’s targets.

¹ Alberta Environment, 2002, “Albertans and Climate Change: Taking Action”, Government of Alberta.

Objective of this report

Alberta Environment has retained MK Jaccard and Associates for the purpose of providing an analysis of climate change mitigation options for Alberta to support the development of the Climate Change Action Plan. MKJA uses a detailed energy-economy model called CIMS to evaluate energy and climate change policies and to determine the cost of reducing greenhouse gas emissions.

In this project, we use the CIMS model to estimate the magnitude of greenhouse gas reductions that would be obtained throughout the Alberta economy when different strengths of policy signals are applied. Policies are characterized using the concept of a *carbon charge*, which represents the financial signal required to stimulate different emissions-reducing actions throughout the economy. As part of the analysis, we show results using *wedge diagrams*, which categorize abatement measures into alternative designations for illustrative purposes. Finally, we also show the likely results of several regulatory policies designed to reduce emissions. This report does not prescribe a specific set of policies that Alberta should implement; its purpose is to provide information on some of the different policy instruments available to Alberta.

Structure of this report

We begin this report with an overview of the methodology used to produce the quantitative results, including a high-level description of the CIMS model that was used for the analysis. We then discuss the assumptions and inputs that were used to develop the reference case forecast that was produced for this report, and present the reference case forecast in detail. The following section presents the detailed analysis of quantitative policy analysis using carbon charges and the results of the regulatory policy analysis.

Methodology

The primary objective of this study is to project the economic and environmental impacts of various options for greenhouse gas policy in Alberta. In order to do this, the CIMS energy-economy model was updated to reflect recent provincial data and trends and used to analyze greenhouse gas charges in Alberta. The model is described very briefly here; a somewhat more comprehensive description of the model is provided in the Appendix.

The CIMS model

The CIMS model, developed by the Energy and Materials Research Group at Simon Fraser University and by MK Jaccard and Associates, simulates the technological evolution of fixed capital stocks (such as buildings, vehicles, and equipment) and the resulting effect on costs, energy use, emissions, and other material flows. The stock of capital is tracked in terms of energy service provided (m² of lighting or space heating) or units of physical product (metric tons of market pulp or steel). New capital stocks are acquired as a result of time-dependent retirement of existing stocks and growth in stock demand. Market shares of technologies competing to meet new stock demands are determined by standard financial factors as well as behavioural parameters from empirical research on consumer and business technology preferences. CIMS has three modules — energy supply, energy demand, and macro-economy — which can be simulated as an integrated model or individually. A model simulation comprises the following basic steps.

1. A base-case macroeconomic forecast initiates model runs. The macroeconomic forecast is at a sectoral or sub-sectoral level (for example, it estimates the growth in total passenger travel demand, or in airline passenger travel demand). The macroeconomic forecast adopted for this study is described in detail in the following section.
2. In each time period, some portion of existing capital stock is retired according to stock lifespan data. Retirement is time-dependent, but sectoral decline can also trigger retirement of some stocks before the end of their natural lifespans. The output of the remaining capital stocks is subtracted from the forecast energy service or product demand to determine the demand for new stocks in each time period.
3. Prospective technologies compete for new capital stock requirements based on financial considerations (capital cost, operating cost), technological considerations (fuel consumption, lifespan), and consumer preferences (perception of risk, status, comfort), as revealed by behavioural-preference research. The model allows both firms and individuals to project future energy and carbon prices with imperfect foresight when choosing between new technologies (somewhere between total myopia and perfect foresight about the future). Market shares are a probabilistic consequence of these various attributes.

FINAL REPORT

4. A competition also occurs to determine whether technologies will be retrofitted or prematurely retired. This is based on the same type of considerations as the competition for new technologies.
5. The model iterates between the macro-economy, energy supply and energy demand modules in each time period until equilibrium is attained, meaning that energy prices, energy demand and product demand are no longer adjusting to changes in each other. Once the final stocks are determined, the model sums energy use, changes in costs, emissions, capital stocks and other relevant outputs.

The key market-share competition in CIMS can be modified by various features depending on the evidence about factors that influence technology choices. Technologies can be included or excluded at different time periods. Minimum and maximum market shares can be set. The financial costs of new technologies can decline as a function of market penetration, reflecting economies of learning and economies of scale. Intangible factors in consumer preferences for new technologies can change to reflect growing familiarity and lower risks as a function of market penetration. Output levels of technologies can be linked to reflect complementarities.

Personal mobility provides an example of CIMS' operation. The future demand for personal mobility is forecast for a simulation of, say, 30 years and provided to the energy demand module. After the first five years, existing stocks of personal vehicles are retired because of age. The difference between forecast demand for personal mobility and the remaining vehicle stocks to provide it determines the need for new stocks. Competition among alternative vehicle types (high and low efficiency gasoline, natural gas, electric, gasoline-electric hybrid, and eventually hydrogen fuel-cell) and even among alternative mobility modes (single occupancy vehicle, high occupancy vehicle, public transit, cycling and walking) determines technology market shares. The results from personal mobility and all other energy services determine the demand for fuels. Simulation of the energy supply module, in a similar manner, determines new energy prices, which are sent back to the energy demand module. The new prices may cause significant changes in the technology competitions. The models iterate until quantity and price changes are minimal, and then pass this information to the macro-economic module. A change from energy supply and demand in the cost of providing personal mobility may change the demand for personal mobility. This information will be passed back to the energy demand module, replacing the initial forecast for personal mobility demand. Only when the model has achieved minimal changes in quantities and prices does it stop iterating, and then move on to the next five-year time period.

Modelling scenarios

The primary purpose of the analysis reported here is to show how different options for greenhouse gas policy instruments could influence greenhouse gas emissions, economic output, and costs of compliance at a sectoral level. In order to determine the greenhouse gas abatement opportunities in Alberta over time, we use the concept of a reference scenario and a policy scenario. The reference scenario shows how the Alberta economy might evolve in the absence of specific new policies to reduce greenhouse gas emissions.

FINAL REPORT

The policy scenario shows how the economy might evolve under a given policy. The difference between the two scenarios is due to the effect of the policy.

Carbon charges represent a generic market-based instrument for GHG reduction, such as an emission tax or a cap-and-trade system (in this case the carbon charge represents the equilibrium permit trading price). This type of policy is generally considered the most economically efficient and effective way to reduce greenhouse gas emissions, because it sends a consistent marginal cost signal throughout the economy. Simulating this type of policy is also useful because it explicitly conveys the strength of policy in consistent units (dollars per tonne of GHG reduced), and allows easy comparison of the results of one simulation to another.

We model several policy scenarios in order to provide a sense of the effect of different levels and trajectories of carbon charges on key outputs. In all scenarios, the carbon price is applied throughout the economy, on both energy related combustion emissions, non-energy emissions, fugitive and flaring emissions, and fixed process emissions.² The price on non carbon dioxide greenhouse gas emissions is based on the 100-year global warming potentials reported by the Intergovernmental Panel on Climate Change.³

Table 1 outlines the scenarios that were modelled. We model four flat carbon charge trajectories, where the price on carbon does not increase or decrease over time. We also model three escalating carbon charge scenarios, where the price on carbon increases over time. The escalating carbon charge scenarios allow firms and individuals to gradually adjust to higher carbon charges and should reduce the probability of economic dislocation during policy implementation, particularly if government communicates the carbon charge schedule to firms and individuals with advanced notice.

Table 1: Policy scenarios modelled in this report

| <i>Scenario</i> | <i>2011-2015</i> | <i>2016-2020</i> | <i>2021-2025</i> | <i>2026-2030</i> | <i>2031-2035</i> | <i>2036-2040</i> | <i>2041-2045</i> | <i>2046-2050</i> |
|-----------------|------------------|------------------|------------------|------------------|------------------|------------------|------------------|------------------|
| P1-F15 | \$15 | \$15 | \$15 | \$15 | \$15 | \$15 | \$15 | \$15 |
| P2-F30 | \$30 | \$30 | \$30 | \$30 | \$30 | \$30 | \$30 | \$30 |
| P3-F60 | \$60 | \$60 | \$60 | \$60 | \$60 | \$60 | \$60 | \$60 |
| P4-F100 | \$100 | \$100 | \$100 | \$100 | \$100 | \$100 | \$100 | \$100 |
| P5-Ea | \$15 | \$30 | \$30 | \$60 | \$60 | \$60 | \$60 | \$100 |
| P6-Eb | \$30 | \$40 | \$50 | \$60 | \$70 | \$80 | \$90 | \$100 |
| P7-Ec | \$50 | \$75 | \$100 | \$150 | \$200 | \$200 | \$200 | \$200 |

Note: All carbon charges are presented in CDN\$2003 / t CO_{2e} and are applied throughout the economy. In the “Scenario” column, we use the letter “F” to denote a flat carbon charge (no increases or decreases over time), and “E” to denote an escalating carbon charge.

In addition to the analysis of carbon charges, we modelled several other policy options. In particular, we modelled the following:

² Because the current version of the CIMS model does not include a sub-model for agroecosystems or waste, the carbon charge is not extended to these sectors.

³ Intergovernmental Panel on Climate Change, 2007, “The physical basis of climate change”, IPCC WG1 AR4 Report.

- **Carbon capture and storage regulation for large industrial facilities.** We model a policy where all large new industrial facilities are required to incorporate carbon and storage by 2015 wherever possible. At the request of Alberta Environment, we modelled this policy in combination with the carbon charge schedule P5-Ea in Table 1.
- **Nuclear electricity generation plant constructed.** We model a scenario in which a 2,200 MW nuclear plant is commissioned to produce electricity for Alberta's grid in 2020.
- **Residential building code implemented.** We model a policy that requires new houses built in Alberta to be certified as Built Green™ Gold by 2010. Built Green™ Gold houses have an EnerGuide rating of at least 77, which represents an energy efficiency improvement of roughly 20 to 25 percent compared to current standard practice (current practice corresponds to an EnerGuide rating of about 68).
- **Vehicle emissions standard for new vehicles.** We model a policy that requires the average greenhouse gas intensity of new vehicles sold in Alberta to be less than a specified level. Table 2 illustrates the standard simulated for this project, and compares it to California's vehicle emissions standard (on which the policy modelled here is based). The key difference between California's standard and the standard modelled for this project is that California's standard applies different emissions requirements to small and large vehicles. The standard simulated for this project requires the average greenhouse gas intensity of all passenger vehicles to be less than a specific level. We also assume there are no changes to the standard after 2016.

Table 2: Maximum average fleet GHG standard modelled in this report

| Year | Maximum average fleet GHG standard (g CO ₂ /km) | | |
|------|--|--------------|------------------|
| | Proposed Regulation in California | | Modelled in CIMS |
| | Passenger Cars / Small Trucks | Large Trucks | S5-VES |
| 2011 | 166 | 243 | 174 |
| 2012 | 145 | 225 | |
| 2013 | 142 | 221 | |
| 2014 | 138 | 218 | |
| 2015 | 133 | 213 | |
| 2016 | 128 | 207 | 160 |

Source: Air Resources Board, California Environmental Protection Agency, 2007.

- **Commercial building code implemented.** We model a policy that requires all new commercial construction to meet LEED Gold™ standards. While commercial buildings can achieve LEED™ certification by incorporating several environmental improvements (e.g., improvements to waste management or a reduction in water use), we only model the standard's effect on energy intensity. We estimate that LEED Gold™ buildings are, on average, 51% more energy

efficient than a building built to the current specifications of the Model National Energy Code of Canada for Buildings.⁴

- **Requirement for electricity to be generated from renewable sources.** We simulate a policy where 20% of electricity must be generated from renewable sources by 2020. Hydroelectric generation qualifies as a renewable source in this policy.
- **A policy package.** We model a policy that combines several of the regulatory policies discussed above. In particular, the policy package includes: 1) the carbon capture and storage regulation, 2) the nuclear plant built in 2020, 3) the new building standards for commercial and residential buildings, and 4) the vehicle emissions standard.⁵
- **A deep reduction policy.** We assess the stringency of carbon charge required to attain a 50% reduction in greenhouse gas emissions from 2005 levels by 2050. For this policy we simulate a ceiling on carbon charges equal to \$300/tonne CO₂e (2003\$).

Model limitations and uncertainties

Like all models, CIMS is a representation of the real world, and so does not represent it perfectly. Even though CIMS is very detailed compared to other models that are used for similar purposes, its broad scope (it represents all energy consumption throughout the economy) requires many simplifying assumptions. The main uncertainties and limitations in the model are:

- **Technological detail and dynamics** – CIMS contains a considerable level of technological detail in each of its sectoral sub-models. This detail enables CIMS to show accelerated market penetration of alternative technologies in response to an energy or climate change policy and to ensure that reference and policy scenarios are grounded in technological and economic reality. While care has been taken in representing the engineering and economic parameters of the many technologies in CIMS, uncertainty exists (particularly in industrial sectors) as to the appropriate cost and operating parameters of specific technologies.

This uncertainty becomes larger over time. While CIMS contains a representation of dynamic technological change that depicts how the costs of new technologies can be reduced through economies of scale and production experience based on historical experience, there is no guarantee that these relationships will hold in the future. In addition, CIMS only contains technological options that are known today (including those that are not yet commercialized). By definition, CIMS

⁴ This is calculated using data on LEED™ buildings in Canada from Canada Green Building Council, 2007.

⁵ The requirement for 20% of electricity to be generated from renewable sources was excluded from the policy package to ease the modelling.

- does not contain a depiction of new technologies that have not yet been invented. As a result, CIMS could miss technological substitution options in later years of the forecast.
- **Behavioural realism** – The technology choice algorithm of CIMS takes into account implicit discount rates revealed by real-world technology acquisition behavior, intangible costs that reflect consumer and business preferences, and heterogeneity in the marketplace. Incorporating behavioral realism is critical in order to predict realistic consumer and firm response to policies, however, incorporating preferences at a detailed level into a model that is technologically explicit is challenging. In addition to the sheer volume of the data requirements, the non-financial preferences of consumers and firms are difficult to estimate, and can change over time. The complexities associated with estimating behavioral parameters, combined with the fact that information cannot be collected for all the technology competitions in CIMS, result in a high degree of uncertainty associated with these parameters overall. The potential for preference change is also a key uncertainty.
 - **Equilibrium feedbacks** - Unlike most computable general equilibrium models (which do not contain technological detail), the current version of CIMS does not equilibrate government budgets and the markets for employment and investment. Also, its representation of the economy's inputs and outputs is skewed toward energy supply, energy intensive industries, and key energy end-uses in the residential, commercial/institutional, and transportation sectors. As a result, it is likely to underestimate the full structural response of the economy to energy and climate change policies.
 - **External inputs** – CIMS requires external forecasts of macroeconomic activity in each subsector, population growth forecasts, and fuel price forecasts on which to base the analysis. These forecasts are uncertain and could affect the results of the simulations. In addition, since no individual forecast is available to provide all key inputs over the period of interest in this analysis, we have adopted inputs from several different sources. We have used respected sources, and attempted to ensure consistency between various sources, but it is likely that the various inputs we use are not perfectly consistent with one another.

The reference scenario

The reference scenario described in this report is based on several external inputs showing how the economy will evolve over the coming 45 years to 2050. Many key inputs underlying the reference scenario are highly uncertain, and if the economy evolves differently than as shown in this reference scenario, energy consumption and emissions will also differ from what we show here. We have used credible sources to guide key inputs wherever possible, but no amount of research allows perfect foresight into the future of the economy. As a result, the scenario described here should be considered just one possible reference scenario. We consider it a reasonable “business as usual” forecast, based on historic trends and research into likely future technological and economic evolution, but the uncertainty remains large. We begin by highlighting our key assumptions, and follow by showing the results of our forecast.

Key economic drivers and assumptions

CIMS uses an external forecast for the economic or physical output of each economic sector to develop the business as usual forecast. For example, CIMS requires an external forecast for the number of residential households, and another for the amount of cement produced in the province. These forecasts can be internally adjusted when a policy is applied. We discuss the forecasts adopted for both the energy supply sectors and the energy demand sectors.

Energy demand sectors

For all energy demand sectors, the external forecast through 2020 is based on the same data used by Natural Resources Canada to develop the national energy outlook in 2006.⁶ For years beyond 2020, the forecast for demand sectors is based on a long-run economic forecast of gross domestic product, population, and labour force participation prepared by Infometrica for the federal government, which is depicted in Table 3.⁷ The population forecast used here is similar to the medium growth scenario developed by Statistics Canada in a recent demographic forecast.⁸

Table 3: Alberta economic and demographic forecast

| | <i>Units</i> | <i>2010</i> | <i>2020</i> | <i>2030</i> | <i>2040</i> | <i>2050</i> |
|------------------------|-----------------------------------|-------------|-------------|-------------|-------------|-------------|
| Gross Domestic Product | <i>billion 2003\$^a</i> | 180.7 | 224.0 | 268.7 | 324.6 | 385.1 |
| Population | <i>thousands</i> | 3,464 | 3,903 | 4,294 | 4,601 | 4,863 |

Note: ^a Gross domestic product is presented in basic prices

⁶ Natural Resources Canada, 2006, “Canada’s Energy Outlook: The Reference Case 2006”, Analysis and Modelling Division, Natural Resources Canada.

⁷ Infometrica, 2007, “Infometrica’s Long-run Reference Population and Productivity Forecast”. Natural Resources Canada also bases its forecast on Infometrica’s macroeconomic and demographic projections.

⁸ Statistics Canada, 2006, “Population Projections for Canada, Provinces, and Territories: 2005-2031”, Demography Division, Statistics Canada.

FINAL REPORT

The residential sector is anticipated to continue fairly rapid growth because of continued population growth in the province. The rate of both population growth and household formation are expected to slow later in the forecast from present levels, when Alberta's population is anticipated to be about one and a half times larger than the current level.

The commercial sector is expected to undergo rapid expansion, driven by expanding economic output in the province. By the end of the forecast period, the commercial sector is expected to be more than double its current size (based on physical building footprint).

Travel demand in the passenger transportation sector is increasing quickly in Alberta, fuelled by growth in population as well as income. These trends are expected to continue in general, but slow throughout the forecast period. Air travel continues to expand in importance, driven by rising incomes in Alberta. In the freight transportation sector, growth is expected to be even faster than in the passenger sector, because of quickly rising GDP and expansion of industrial output in particular.

Like other demand sectors, output is expected to grow in the industrial manufacturing sector. The demand for industrial minerals (cement and lime products) is expected to be particularly robust throughout the forecast period, while growth in the pulp and paper and chemical sectors is expected to be more muted. Continued growth is also expected in the other manufacturing sector, which is a catch-all sector that includes most smaller manufacturing facilities.

Energy supply sectors

The main energy supply sectors in CIMS include crude oil extraction, natural gas extraction and processing, petroleum refining, electricity generation, and coal mining. For crude oil and natural gas, we rely on external forecasts of production, because a large percentage of Alberta's production is exported to other regions. For petroleum refining, electricity generation, and coal mining, we base the supply forecast on Alberta's projected energy demand, and add in an external forecast of net exports of each commodity to calculate total production.

Alberta's crude oil production forecast is shown in Figure 2 and is based on the moderate growth case of the Canadian Association of Petroleum Producers 2007 report.⁹ The output of conventional crude oil (light & medium, and heavy) between 2025 and 2050 is projected to continue decline due to existing reserve depletion. By 2050, conventional crude oil production is expected to account for only a small amount of total production.

Conversely, production of unconventional crude oil from Alberta's oil sands is forecast to increase dramatically during the forecast period. Total production of crude oil from the oil sands is forecast to reach about 4.1 million barrels per day by 2025 and about 5.7

⁹ Canadian Association of Petroleum Producers, 2007, "Crude oil forecast, markets, and pipeline expansions", June 2007. CAPP's forecast extends to 2025; after 2025, production in the sector is assumed to continue to grow slowly for unconventional crude oil, and to continue to decline for conventional crude oil. The forecast after 2025 is very uncertain, since projects are not announced with this much lead time. CAPP's recent forecast is higher than the forecast adopted in NRCan's 2006 Energy Outlook.

FINAL REPORT

million barrels per day by 2050, a five-fold expansion in capacity from today's levels. Particularly rapid growth in the industry is expected in the coming two decades, both in thermal (in-situ) operations and in mining and upgrading operations.

According to the Alberta Energy and Utilities Board, the volume of crude bitumen in the oil sands is estimated to be approximately 1.6 trillion barrels, with 175 billion barrels recoverable under current economic conditions and with current technologies. The growth forecast of oil sands development in our model has taken this resource constraint into consideration. During the modelling period, the forecasted cumulative output of in-situ bitumen and synthetic crude oil is about 72 billion barrels.

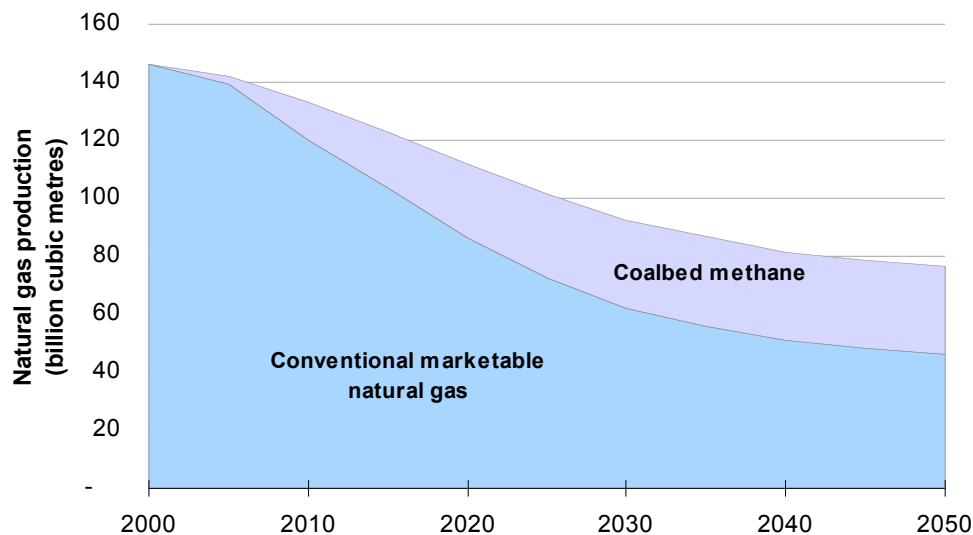

Figure 2: Crude oil supply forecast

Source: Forecast based on Moderate Growth case from Canadian Association of Petroleum Producers, 2007, "Crude oil forecast, markets, and pipeline expansions", June 2007.

Marketable natural gas production in Alberta between 2000 and 2015 is based on the Alberta Energy and Utility Board's 2006 forecast. The growth rate forecast between 2015 and 2025 comes from a recent National Energy Board Report.¹⁰ Due to the depletion of conventional oil and gas reserves in Alberta, natural gas supply in Alberta is projected to continue to decline afterwards. However, the development of coal bed methane resources could offset part of the natural gas supply reduction during the modelling period. Figure 3 shows the forecast of marketable natural gas production that was adopted for this report. The figure shows that even with a substantial increase in coalbed methane supply, overall natural gas production is expected to decline steeply in the province. Because coalbed methane is a relatively new resource, the forecast for extraction of coalbed methane adopted for this reference scenario is very uncertain.

Figure 3: Natural gas supply forecast

Source: Forecast based on Alberta Energy Utilities Board, 2006, “Alberta’s Energy Reserves 2005” and “Supply/Demand Outlook 2006-2015”; National Energy Board, 2003, “Canada’s Energy Future: Supply and Demand Forecast to 2025”; National Energy Board, 2004, “Canada’s Oil Sands: Challenges and Opportunities to 2015”.

The forecast of output for the electricity generation sector is based on the calculated demand from all other sectors in the model, and is adjusted to include net exports of electricity.¹¹ The forecast of output from the electricity generation sector does not include non-utility electricity generation, which is accounted for separately in the other sub-models (for example, electricity production by cogeneration in the oil sands is accounted for in the upstream oil sub-model).

Figure 4 shows the reference case electricity generation by fuel type. Total utility electricity generation is expected to increase only slightly in the coming decade, as non-utility generation increases rapidly.¹² Towards the end of the forecast period, utility electricity generation is forecast to increase again, such that by 2050, the electricity sector will be producing almost twice as much electricity as in 2005. In the reference case, the model forecasts that most electricity generation will continue to be provided from coal. Renewables (particularly wind, small hydro, and biomass) could provide a more significant portion of electricity generation by 2050.

¹¹ Net exports of electricity are based on the recent Natural Resources Canada energy outlook through 2020 and are assumed to remain at historic levels thereafter.

¹² AMEC Americas Limited, 2006, “Alberta 10-year Generation Outlook”, Prepared for Alberta Electric System Operator.

Figure 4: Reference case utility electricity generation by fuel type

In the policy scenarios, we assume that net exports of electricity and coal remain fixed at the levels in the reference case. For crude oil and natural gas in the policy scenarios, we assume that total provincial production of the commodity is fixed and adjust net exports based on the difference between total production and domestic demand.¹³

Table 4 summarized the reference case economic output forecast that is adopted for this forecast. As has been emphasized throughout, this forecast reflects historic and anticipated future trends, but is highly uncertain, particularly in the later years of the forecast.

¹³ Although this assumption is likely imperfect, the US Energy Information Administration projects that international demand for crude oil and natural gas is likely to remain robust even with the introduction of climate change abatement policies. See Energy Information Administration, 1998, “Impacts of the Kyoto Protocol on US Energy Markets and Economic Activity”, United States Department of Energy.

Notes: ^a chemical product output is the sum of chlor-alkali, sodium chlorate, hydrogen peroxide, ammonia, methanol, and petrochemical production

^b industrial mineral output is the sum of cement, lime, glass, and brick production

^c pulp and paper output is the sum of linerboard, newsprint, coated and uncoated paper, tissue and market pulp production

^d natural gas production includes coalbed methane

Energy prices

CIMS also requires an external forecast for fuel prices. As for sectoral output, fuel prices can change while a policy scenario is running if the policy induces changes in the cost of fuel production. Reference case prices for most fuels through 2020 are derived from the recent energy outlook published by Natural Resources Canada (the industrial and electricity coal price forecasts were derived from forecasts by the US Environmental Protection Agency). For years after 2020, real oil and coal prices are assumed to remain flat, while the real natural gas price is assumed to gradually increase until it reaches an assumed future import price of liquefied natural gas, reflecting declining domestic supplies of natural gas. Table 5 shows the fuel price forecast that was used to develop the reference case forecast in this report. Like the other forecasts that are used as inputs to CIMS, it should be recognized that the fuel price forecast adopted here is highly uncertain, particularly in the longer term. In addition, the fuel price forecasts that we have adopted are intended to reflect long-term trends only, and will not reflect short-term trends caused by temporary supply and demand imbalances.

Table 5: Reference case price forecast for key energy commodities

| | <i>Units</i> | <i>2010</i> | <i>2020</i> | <i>2030</i> | <i>2040</i> | <i>2050</i> |

Note: All prices in Canadian dollars.

Policies included in the reference case

Both the federal and provincial governments have developed energy and climate policies over the past few years. We have attempted to include the most important of these in the reference case developed here. In particular, we include:

- The federal renewable power production incentive, which provides \$0.01/kWh of renewable energy production during the first 10 years after commissioning of a new renewable energy facility;
- The Alberta specified gas emitters framework, which requires facilities that emit at least 0.1 Mt of CO₂e in Alberta to reduce emissions intensity by 12% compared to a 2003-2005 baseline (there is a provision for purchases of credits from offset projects and from a technology fund at \$15/t CO₂e);
- The federal ethanol excise tax exemption of \$0.10/L and the provincial \$0.09/L tax exemption for ethanol;
- The federal minimum energy performance standards for household appliances, including furnace regulations requiring 90% efficiency in new natural gas furnaces starting in 2009;
- The federal ecoENERGY for Transport policy, which provides up to \$2,000 towards the purchase of a high efficiency vehicle;
- The federal ecoENERGY for Efficiency policy, which provides incentives towards the replacement of lower efficiency energy consuming equipment with more efficient equipment.

Reference case energy and emissions outlook

Based on the key economic assumptions highlighted above, we used CIMS to develop an integrated reference case forecast for energy consumption and greenhouse gas emissions through 2050. The CIMS model captures virtually all energy consumption and production in the economy.

The reference case forecast for total energy consumption is shown in Table 6, while Table 7, Table 8, and Table 9 show natural gas, refined petroleum product, and electricity consumption, respectively. The residual energy consumption of other fuel types (total minus natural gas, refined petroleum product, and electricity) is not explicitly shown in this report.

Table 6: Reference case total energy consumption

| | <i>Units</i> | <i>2010</i> | <i>2020</i> | <i>2030</i> | <i>2040</i> | <i>2050</i> |
|------------------------|------------------|--------------|--------------|--------------|--------------|--------------|
| Demand Sectors | | | | | | |
| Residential | <i>PJ</i> | 191 | 206 | 211 | 204 | 176 |
| Commercial | <i>PJ</i> | 152 | 178 | 208 | 241 | 267 |
| Transportation | <i>PJ</i> | 414 | 491 | 565 | 649 | 693 |
| Manufacturing Industry | <i>PJ</i> | 305 | 335 | 381 | 407 | 429 |
| Supply Sectors | | | | | | |
| Crude Oil | <i>PJ</i> | 944 | 1,848 | 2,024 | 2,124 | 2,252 |
| Natural Gas | <i>PJ</i> | 416 | 330 | 248 | 200 | 159 |
| Coal Mining | <i>PJ</i> | 8 | 11 | 11 | 12 | 15 |
| Electricity Generation | <i>PJ</i> | 553 | 538 | 554 | 642 | 861 |
| Petroleum Refining | <i>PJ</i> | 95 | 122 | 156 | 207 | 253 |

| Total | <i>PJ</i> | 3,078 | 4,058 | 4,357 | 4,687 | 5,106 |

Note: Producer consumption of energy (e.g., consumption of hog fuel in the pulp and paper sector or refinery gas in the petroleum refining sector) is included in these totals. Energy consumption in the electricity generation sector includes consumption of water, wind, nuclear, and biomass using coefficients adopted from the International Energy Agency.¹⁴

¹⁴ International Energy Agency, 2007, “Energy Balances of OECD Countries: 2004-2005”. Renewable electricity generation is assumed to require 1 GJ of energy (e.g., wind, hydro) for each GJ of electricity generated. Nuclear electricity generation is assumed to require 1 GJ of energy for each GJ of thermal energy generated.

Based on total energy consumption as well as on process emissions in the industrial sector and supply sectors, we calculate the greenhouse gas emissions associated with the reference case forecast, as shown in Table 10. While the CIMS model captures virtually all energy consumption and production in the economy, it does not capture the methane and nitrous oxide emissions from the agriculture and waste sectors. In 2005, these sectors represented about 8% of total greenhouse gas emissions, measured on an equivalent global warming potential basis. As a result, the forecast presented here will underestimate the actual GHG emissions in the Alberta economy somewhat.

Table 10: Reference case greenhouse gas emissions

| Total | <i>Mt of CO₂e</i> | 235 | 311 | 328 | 353 | 387 |

Note: CIMS does not include a waste or agroecosystems model and so does not include emissions from these sectors.

Table 10 shows that in the absence of new policies to control greenhouse gas emissions, emissions are expected to grow from current levels in all sectors of the Alberta economy except natural gas extraction. Especially strong growth is expected in the crude oil sector, as a result of rapidly expanding output in this sector.

The reference case in context

Figure 5 compares the total greenhouse gas emissions reported in this reference case to those in the Natural Resources Canada reference case and to a recent forecast by Infometrica Ltd. prepared for the federal government. With the NRCan and Infometrica forecasts adjusted to remove emissions from agroecosystems and waste, the three forecasts are generally quite similar. All show Alberta’s energy-related greenhouse gas emissions increasing dramatically over time from about 150 Mt in 1990 to around 300 Mt by 2020, and around 400 Mt in 2050. The main reason for differences between the NRCan and CIMS forecasts is recent changes to the crude oil output forecast released by the Canadian Association of Petroleum Producers.

Total energy consumption is also very similar between the NRCan and CIMS forecasts, although there are some differences in the projections at a sectoral level.

Figure 5: Reference case greenhouse gas emissions

Note: This chart excludes emissions from agroecosystems and waste, which in 2005 represented about 8% of the Alberta total and is forecast (by Natural Resources Canada) to represent 6% of the total in 2020. The contribution from these sectors as a proportion of the total is likely to continue to decline over time. Historic emissions in this chart (1990-2005) are from Environment Canada’s 2005 Greenhouse Gas Inventory.

Quantitative policy analysis

Context

The research summarized in this section is a quantitative exploration of the effect of several alternative greenhouse gas policies on the Alberta economy. The section begins with an analysis of policies that employ a carbon charge. Carbon charges capture the strength of a market-based policy signal required to achieve a given level of emissions reductions in a given timeframe. The carbon charges modelled here are roughly equivalent to an economy-wide tax on greenhouse gas emissions, or the selling price of emissions permits in an emissions cap-and-trade system.

The analysis is carried out under several key assumptions, including:

- The analysis in this report is aimed at understanding the potential for reducing Alberta's greenhouse gas emissions. As a result, we restrict the analysis to domestic GHG reductions, and allow no purchases of international offset credits.
- The current version of CIMS does not include a representation of agroecosystems or the waste sector. As a result, the results shown here do not include abatement opportunities or emissions from these sectors.
- The technologies in CIMS are limited to foreseen technologies that are likely become commercially available in the timeframe of the analysis. However, high GHG prices could also stir the invention and commercialization of currently unforeseen low GHG technologies and processes. CIMS does not simulate the potential impact of these technologies, so it is likely that the modelling has missed some technological developments that could lower the long-term cost of carbon mitigation.
- Carbon capture and storage (CCS) is 90% effective at removing carbon dioxide from a flue gas stream. After including an energy efficiency penalty, a technology with CCS has approximately 15% of the emissions of an equivalent technology without. Future developments may improve the capture efficiency of CCS; these are not included in the modelling here.
- No nuclear energy is allowed in Alberta either for thermal energy in the upstream oil sector or for electricity generation. We made this assumption because the development of nuclear energy is a political decision as much as an economic one, and therefore difficult to simulate in an economic model. We test the results to the sensitivity of this assumption by including a run where nuclear electricity is generated in Alberta starting in 2020.
- All of the carbon charge policies simulated here are revenue neutral from a fiscal perspective, meaning that any revenue attained from the carbon charge is returned to the sector that paid it. As a result, a sector as a whole does not incur any net costs associated with paying an emissions tax, but only incurs the investment costs associated with abating its emissions.

FINAL REPORT

- Policies that are introduced in Alberta do not change the world price for crude oil or the continental price for natural gas, and do not change the overall output of these sectors (although, since domestic demand can change, the net exports of these commodities can change).

The modelling in this report only accounts for the cost of emissions abatement. Accounting for the human and environmental benefits of emissions abatement requires a separate methodology and is beyond the scope of this report. Because the benefits of emissions abatement are not systematically compared to the costs in this analysis, we are not able to make recommendations as to the optimal level of GHG reductions; this can only be done through careful comparison of the costs and benefits. Instead, the aim of this report is to conduct analysis of the effect of alternative policies on GHG emissions in Alberta. The results should be interpreted in this context.

Environmental impact of GHG charges

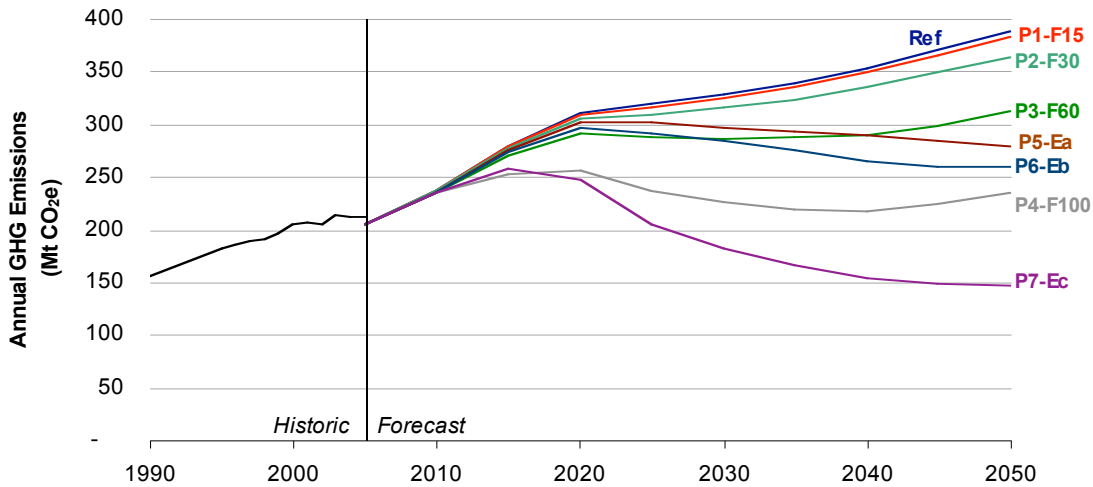

Effect of greenhouse gas charges on provincial emissions

Using the CIMS model, we simulated several greenhouse gas charges to capture the effect of climate change policy on both Alberta's emissions and economy. The actual greenhouse gas charge trajectories that were simulated are shown in Table 1, and range from a very modest GHG charge that is maintained at the same level throughout the simulation period to a charge that starts low and rises gradually to a much higher level over time.

Figure 6 shows the projected effect of the various levels of charges on greenhouse gas emissions in Alberta.¹⁵ In the absence of new climate change policies, GHG emissions are projected to reach about 390 Mt CO₂e by 2050 (excluding emissions from agroecosystems and waste) – an increase of more than 80 percent over 2005 levels. The effect of carbon charges we modelled here range from modest reductions in emissions from the reference case to a 62% reduction from the reference case in 2050 in the most aggressive scenario. However, because Alberta's GHG emissions are projected to increase rapidly in the reference case, only the most aggressive of the policies simulated stabilized Alberta's emissions at its 1990 levels by 2050.

¹⁵ The current version of the CIMS model does not include sub-models for agroecosystems or waste, and so all results here exclude emissions from these sectors. In 2005, these sectors accounted for about 8% of Alberta's greenhouse gas emissions. In the future, the relative importance of these sectors is likely to decrease (even as absolute emissions from these sectors is likely to continue to increase).

Figure 6: GHG emissions in the policy scenarios, excluding emissions from agroecosystems and waste

Source: Historic data are from Environment Canada, 2007, “Greenhouse Gas Inventory”.

Figure 6 highlights the importance of capital stock inertia on greenhouse gas emissions. In many sectors of the economy, and in particular the heavy industrial and energy supply sectors, capital equipment lasts for many decades after it is purchased. As a result, it can take several decades for the economy to come to equilibrium after a climate change policy is first applied. Of particular importance is that greenhouse gases as far forward as 2050 can be significantly influenced by the type of policy that is applied today, since some of the equipment that is installed today will remain in service in 2050. If a relatively weak climate policy is applied today, achieving significant GHG reductions by 2050 will be significantly more challenging.

Table 11 shows the emissions reductions by sector for all the carbon charge scenarios we modelled. The values in the table represent a reduction from the reference case in a given year (e.g., the P4-F100 policy reduces Alberta’s GHG emissions in 2050 by 152 Mt CO_{2e} from the reference case in 2050). The table shows that the emissions reductions in Alberta are likely to be concentrated in the crude oil, electricity generation, and transportation sectors. These sectors account for 83% of Alberta’s GHG emissions in the reference case in 2050, and represent 89% of the reductions when a \$100/tonne CO_{2e} carbon charge is applied.

Emissions reductions are especially concentrated in the crude oil and electricity generation sectors in both the \$60 and \$100/tonne CO_{2e} simulations. When carbon charges reach approximately \$50 to \$75/tonne CO_{2e}, we project that carbon capture and storage begins to become economically viable in these sectors, and the relatively widespread adoption of CCS at higher carbon prices causes large GHG reductions.

The run where carbon charges are maintained at \$15/t CO_{2e} has very little effect on emissions, because the Specified Gas Emitters Framework already provides this signal to about 45% of the economy, and because the charge is low.

The environmental impact caused by greenhouse gas emissions is associated more with their cumulative stock in the atmosphere than with their annual flow into the atmosphere, because GHG emissions reside for long periods in the atmosphere. As a result, the impact of Alberta's greenhouse gas emissions on the climate in 2050 will be determined more by the cumulative emissions between today and 2050 than by the annual emissions in 2050.¹⁶

¹⁶ By contrast, for a flow pollutant like sulphur dioxide, the human health and environmental impact in 2050 is strongly related to emissions of sulphur dioxide in 2050.

FINAL REPORT

Figure 7 shows the estimate of cumulative GHG emissions from 2008 to 2050 for the reference case and for each of the policies analyzed. In the reference case, cumulative emissions through 2050 are projected to be 13.8 Gt CO₂e (13.8 billion tonnes CO₂e), whereas in the most aggressive policy scenario (P7-Ec), cumulative emissions are 8.4 Gt CO₂e, or 40 percent lower than in the reference case. Cumulative emissions are influenced by a combination of the strength of the carbon charge and the period in which the carbon charge is implemented. When the strength of the policy does not change over time (as for each of the flat carbon charge scenarios), the stronger carbon charges yield lower cumulative emissions. When the trajectory of carbon prices is changed – as in the P4-F100 and P5-Ea scenarios which both reach \$100/tonne CO₂e in 2050 – cumulative emissions are influenced by the timing of the carbon charge. In P4-F100, the carbon charge reaches \$100/tonne CO₂e earlier in the simulation, and therefore exerts greater influence over the evolution of capital stocks purchased early in the simulation. As a result, cumulative emissions in the P4-F100 scenario are 2.2 Gt CO₂e (18%) lower than in P5-Ea.

Figure 7: Cumulative emissions from 2008 to 2050, excluding emissions from agroecosystems and waste

Greenhouse gas reduction “wedge” diagram

A wedge diagram is a useful heuristic because it shows the relative contribution of different actions in reducing total greenhouse gas emissions from their business as usual trend. In most cases, wedges are presented based on the *technical potential* for greenhouse gas reductions. While this can be a useful concept, it doesn’t capture the relative cost of different actions, the behaviour and preferences of firms and individuals, the interaction between different actions, or the types and stringency of policies that might be necessary to trigger the actions.

Using CIMS, we present a wedge diagram for each policy based on the estimated response of firms and individuals to each of the carbon charges that were modelled. Because CIMS is an integrated model in which firm and consumer behaviour has an

empirical basis, the results account for preferences and behaviour, the relative cost of different actions, and the interaction of actions.

Figure 8 and Figure 9 show the wedge diagrams for each policy simulated. Figure 8 illustrates a standard wedge diagram, where the top of the stack of wedges corresponds to the reference case greenhouse gas emissions and each wedge illustrates the action undertaken to reduce emissions to their final level in the policy scenario. Figure 9 only illustrates the wedges (and omits the final GHG emissions after the policy has been applied) to highlight the actions that attain the emissions reduction in each policy scenario. Note that in Figure 9, the units on the y-axis have been changed so that the figures can be interpreted more clearly. We include the same wedge diagrams where the y-axis is unchanged in Appendix D.

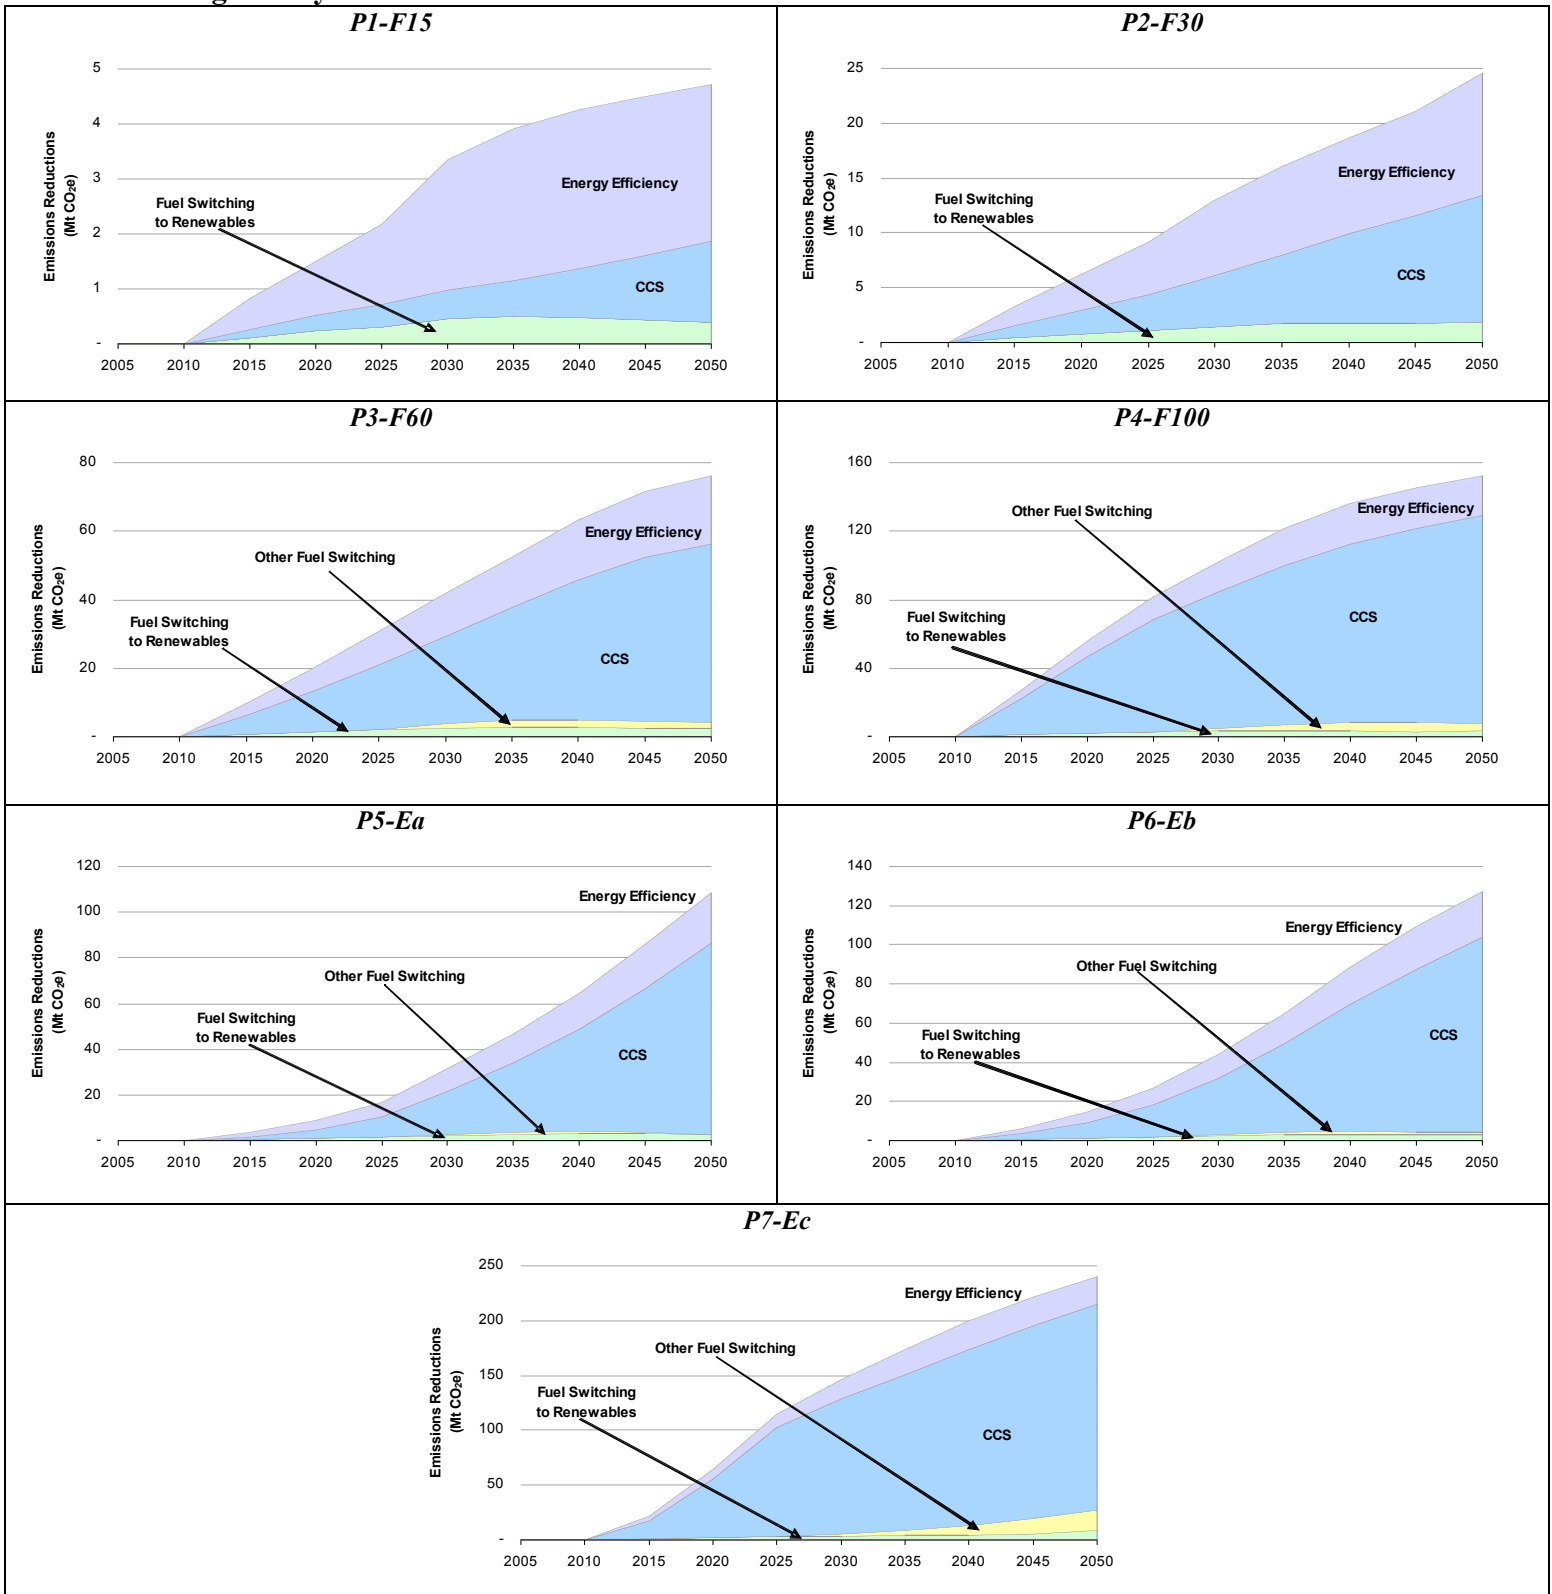

Each wedge below corresponds to reductions of greenhouse gas emissions relative to the reference case as a result of key actions. The top wedge labelled “Energy Efficiency” represents the greenhouse gas reductions caused by increases in energy efficiency. Energy efficiency improves significantly in the reference case, and it should be noted that the wedge shown here only depicts the energy efficiency savings compared to the reference case. The wedge labelled “CCS” represents the greenhouse gas reductions from carbon capture and storage. The wedge labelled “Fuel Switching to Renewables” captures the greenhouse gas reductions associated with switches from fossil fuels to renewables for electricity generation (including wind, hydroelectricity, solar power, and biomass), for heating (solar thermal), and for transportation (including ethanol and biodiesel). The wedge labelled “Other Fuel switching” captures the greenhouse gas reductions associated with switching from more GHG-intense fossil fuels like coal to less GHG-intense fossil fuels like natural gas, as well as switches from fossil fuels to electricity. In Figure 8, the wedge entitled “Policy Emissions” represents the emissions that remain after the policy has been implemented.

Figure 8: Wedge diagram for P7-Ec, excluding emissions from agroecosystems and waste

FINAL REPORT

Figure 9: GHG reduction wedge diagrams for each policy, excluding emissions from agroecosystems and waste

FINAL REPORT

The relative size of the GHG reduction wedges varies depending on the strength of the policy. In policy scenarios with low carbon charges – P1-F15 and P2-F30 – emissions reductions are attained mostly through actions to improve energy efficiency and fuel switching to fuels with low GHG intensity. As the carbon charge strengthens, an increasing amount of emissions reductions are attained through CCS. As discussed above, we project that CCS becomes an economically viable abatement option for carbon charges above approximately \$50 to \$75/tonne CO₂e.

Appendix C disaggregates the wedge analysis for each policy run by sector.

Sector specific results

In order to improve understanding of the results, we present detailed results at a sectoral level using key indicators of energy consumption and greenhouse gas emissions. Where possible, we put the indicators in context using historical data. In some sectors, historical indicators are not available due to the confidential nature of energy and greenhouse gas data (this is particularly the case in the industrial sector and in the oil and gas sector).

In each of the figures, we only illustrate the results for the reference case as well as policy scenarios P2-F30, P4-F100, P5-Ea, and P7-Ec. This was done to improve readability of the figures. Indicators for the other policy scenarios are available in the appendix. In order to ease the interpretation of figures where the trends are similar between policies, we only label the reference case and the strongest carbon charge scenario (P7-Ec). The unlabelled policy scenarios follow the order from the reference case to the strongest carbon charge, unless otherwise noted (the line closest to the reference case is P2-F30, followed by P5-Ea, P4-F100, and P7-Ec (which is labelled)).

Residential sector

In the residential sector, space heating and water heating account for approximately 88% of total energy consumption and almost all of the direct GHG emissions. As illustrated in Figure 10 through Figure 13, both space heating and water heating are expected to have significant improvements in energy and GHG intensity in the reference case. The improvements in space heating are largely due to the retirement or retrofit of old houses, which are generally less efficient than new houses, as well as regulations that require new natural gas furnaces to have an efficiency of at least 90%. The improvements to water heating are smaller than those for space heating, and are largely due to the turnover of less efficient old water heating equipment.

Figure 10 through Figure 13 illustrate that energy efficiency and GHG intensity improve as a result of the implementation of a carbon charge. GHG intensity generally improves more than energy efficiency as a result of the policy. The policies induce both energy efficiency and fuel switching actions, and switching to low emissions fuels reduces emissions but does not necessarily reduce energy consumption. At the end of the simulation in the P4-F100 scenario, we forecast that the energy and GHG intensity of space heating will be 29% and 61% below the reference case, respectively. The energy

FINAL REPORT

and GHG intensity of water heating is projected to be 17% and 32% below the reference case, respectively.¹⁷

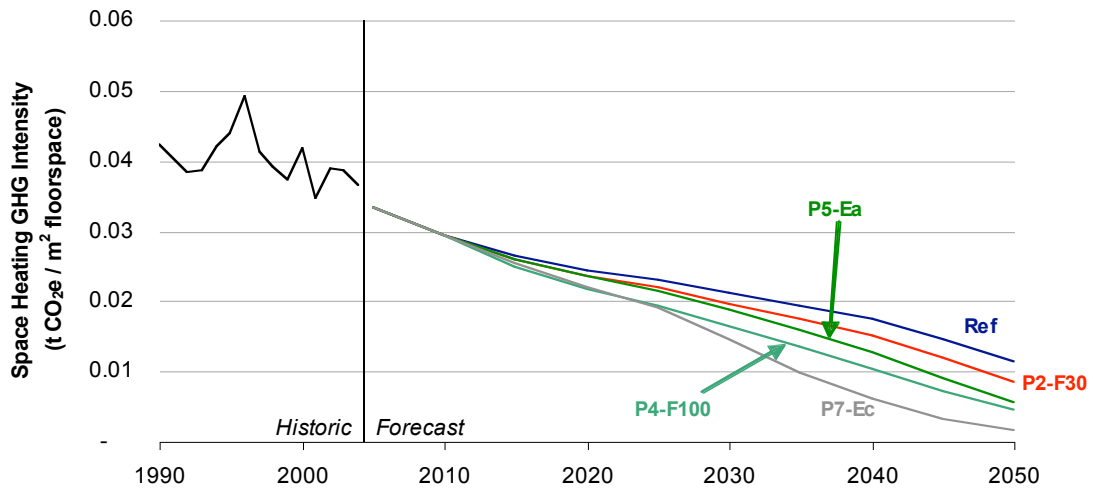

Figure 10: Residential space heating energy intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

¹⁷ Historic fluctuations in energy and GHG intensity are due largely to fluctuations in annual heating degree days. The figures also show a gap between the historic and forecast data because the historic data ends in 2004 and the forecast from CIMS begins in 2005.

Figure 11: Residential space heating direct GHG intensity

Figure 12: Residential water heating energy intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Figure 13: Residential water heating direct GHG intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Commercial sector

Figure 14 and Figure 15 illustrate the energy and GHG intensity of the commercial sector in the reference and policy scenarios. Energy intensity is expected to improve in the reference case as a result of the turnover of building shells as well as the turnover of heating systems. GHG intensity is expected to improve significantly, partially due to the improvements in energy efficiency, but also due to fuel switching from natural gas to electricity as a result of higher natural gas prices.

In the P4-F100 scenario, energy and GHG intensity decline by 9% and 39%, respectively, compared to the reference scenario in 2050. As in the residential sector, the decline in GHG intensity exceeds the decline in energy intensity due to fuel switching from natural gas to electricity, which does not necessarily reduce energy consumption, but reduces direct emissions.¹⁸

¹⁸ Historic fluctuations in energy and GHG intensity are due largely to fluctuations in annual heating degree days.

Figure 14: Commercial building energy intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Figure 15: Commercial building direct GHG intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Transportation sector

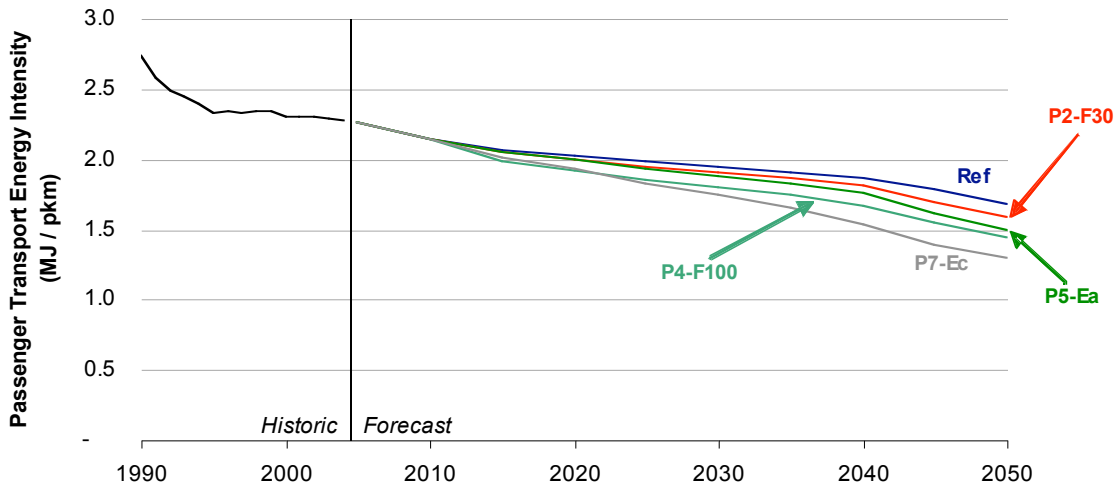

Figure 16 and Figure 17 show the energy and GHG intensity of passenger transportation; and Figure 18 and Figure 19 show the intensity of passenger vehicles (in the figures, “vkm” refers to vehicle-kilometres travelled and “pkm” refers to passenger-kilometres travelled). The key difference between the two metrics is that the former includes the effect of mode switching (e.g.: switching to transit or a high occupancy vehicle); while the latter represents the intensity of passenger vehicles. The reference case shows significant declines in the energy and GHG intensities of both passenger and vehicle transport. We also show a larger decline in the GHG intensity of vehicle transport

FINAL REPORT

between 2040 and 2050. CIMS simulates a modest penetration of low emissions vehicles (e.g., advanced hybrid vehicles plug-in hybrid electric cars and trucks) during these years; however we recognize that the penetration of these vehicles is highly uncertain.

In each of the policy scenarios, energy efficiency actions (e.g., purchasing more efficient vehicles) and fuel switching (e.g., gasoline to ethanol or electricity) account for the largest portion of emissions reductions. Furthermore, energy efficiency actions are more important at the beginning of the simulation, and fuel switching actions become more important later in the simulation, because it may take several years to research and develop the infrastructure for vehicles that consume fuels other than gasoline. In 2050 in the P4-F100 scenario, the GHG intensity of passenger transport declines by 24% compared to the reference case.

Figure 18: Passenger vehicle energy intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

FINAL REPORT

Figure 19: Passenger vehicle GHG intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Figure 20 and Figure 21 show the energy and GHG intensity of freight transportation. The reference case illustrates small declines in intensity over time, due mostly to the gradual turnover of freight trucks. In the policy scenarios, the reductions are mostly due to energy efficiency improvements, with a small amount of mode switching from road transportation to rail.

Figure 20: Freight transportation energy intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Figure 21: Freight transportation GHG intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Electricity generation sector

Figure 22 and Figure 23 illustrate the energy and GHG intensity of electric generation. In the reference case, energy and GHG intensity decline largely due to improved efficiency at new coal and natural gas plants, as well as an increased penetration of renewables in the generation mix – in 2050, we forecast that about 13% of electricity is generated from renewables (including wind, hydroelectricity, and biomass).

In the policy scenarios, energy intensity increases while GHG intensity declines. In 2050 in the P4-F100 scenario, the energy intensity of electric generation increases by 10%, while GHG intensity declines by 63% compared to the reference case. High carbon prices are projected to lead to larger portions of CCS and renewables in the generation mix. While CCS reduces GHG intensity, it increases energy intensity due to the greater energy requirements of capturing and storing carbon dioxide.

Figure 22: Electricity generation energy intensity

Source: Historic data from NRCan’s “Canada’s Energy Outlook”, 2007.

Figure 23: Electricity generation GHG intensity

Source: Historic data from NRCan’s “Canada’s Energy Outlook”, 2007.

Industrial manufacturing sectors

Figure 24 illustrates the energy consumption of the industrial sectors excluding industrial minerals; and Figure 25 illustrates the projected GHG emissions from all industrial sectors. In Figure 24, we exclude the industrial minerals sector because historic data for this sector are confidential. The forecast of energy consumption in the industrial manufacturing sectors does not correspond perfectly to historic data because CIMS includes the energy consumption forecasts of non-purchased fuels – such as black liquor, hog fuel, and still gas – but historic data on these fuels is unavailable, confidential or aggregated into other categories. Therefore, there is a small discrepancy between our

FINAL REPORT

forecast and historic data. We also do not compare our forecast of GHG emissions to historic data because a breakdown of emissions into categories comparable to CIMS is not available from Environment Canada’s Greenhouse Gas Inventory.

Figure 24 shows that carbon charges are unlikely to have a large effect on industrial energy consumption. The reductions in GHG emissions as a result of a policy are largely the result of fuel switching to lower emissions fuels – i.e., coal to natural gas or natural gas to electricity. Energy efficiency and CCS actions account for most of the remaining emissions reductions.

Figure 24: Industrial energy consumption (excludes industrial minerals)

Figure 25: Industrial GHG emissions (includes industrial minerals)

FINAL REPORT

Crude oil sector

The crude oil sector is expected to experience significant increases in production over the simulation period, as well as a rapid shift from conventional oil towards unconventional oil. We illustrate the energy and GHG intensity of the oil sands sectors in Figure 26 and Figure 27. Both of these figures include upgrading of mined bitumen into synthetic crude oil; historic data is not available for comparison. The reference case illustrates small declines in both energy and GHG intensity due to the retirement of old capital stock and its replacement with more efficient stocks. In the policy scenarios, energy intensity increases slightly while GHG intensity declines relative to the reference scenario. In 2050 in the P4-F100 scenario, energy intensity increases by 7% while GHG intensity declines by 42%, relative to the reference scenario. Similar to the electricity generation sector, the adoption of CCS reduces emissions intensity, but increases energy intensity.

Figure 26: Oil sands energy intensity

Figure 27: Oil sands GHG intensity

Economic impact of GHG charges

Overall economic impact

There is considerable debate about the appropriate measure for estimating the cost of greenhouse gas mitigation policies and actions. In this report, we present the cost of GHG abatement in terms of the effect on gross provincial product (GDP). This measure is useful because it is a widely reported measure of total economic output. However, several caveats should be made as to the appropriateness of this measure to guard against misinterpretation:

- CIMS is not a general equilibrium model, and focuses mostly on key energy-consuming sectors of the economy. In calculating the impacts of a policy on gross domestic product, by necessity we implicitly assume that other economic activity is unaffected by policies. Furthermore, CIMS does not capture the effects of a GHG policy on the wage rate or capital markets. Therefore, the estimates of GDP provided here should be interpreted as the impacts on economic activity that would occur if the activity from sectors excluded from CIMS is held constant. In reality, a GHG policy is likely to have feedbacks on activities excluded from CIMS. These could be positive or negative. Box 1 provides an example of how gross domestic product is calculated in this report, and it discusses some of the limitations of this method.

Box 1: GDP calculation example

Consider a policy that requires all new residential construction to meet the Built Green Gold™ standard. Because more energy efficient houses are likely to cost more, expenditure on residential construction is likely to increase as a result of the policy, increasing GDP. At the same time, household expenditure on energy will decrease, decreasing GDP. These components of GDP are captured in the CIMS model used for analysis here.

If the policy requires significant capital expenditure by households, other dynamics may be present that are not captured by CIMS, and which may bias the calculation of GDP reported here. First, if the household spends more on construction, it will have a smaller budget for other expenditures on goods (e.g., televisions, vehicles) and services (e.g., restaurants, accommodations). A reduction in expenditure in these sectors could reduce the output of these sectors (and also reduce the demand for goods and services by these sectors), which could reduce GDP (depending on whether the goods and services are imported or produced domestically). Second, if the household spends more on construction, there could be a feedback effect on the interest rate, which would affect expenditures throughout the economy. Third, the policy could have an affect on the labour market, which could affect the household budget as well as the use of labour throughout the economy.

Since CIMS only includes the direct effects of a policy on GDP, and none of the indirect feedbacks, it is likely biased. Without using a general equilibrium model for the entire economy, it is impossible to predict the direction of the bias. As a result, *the GDP impacts reported here should not be used as estimates of the policy on the GDP of the*

total economy, but estimates of the impact of a policy on the GDP of sectors covered by CIMS, with all else held constant. In reality, as discussed, all else is unlikely to be held constant.

- While gross domestic product is a standard measure of overall economic activity, it is not a measure of welfare. GDP is roughly analogous to the price of all goods and services consumed multiplied by the physical output of these goods and services.¹⁹ In the analysis conducted here, the price of many goods and services throughout the economy is forecast to increase as a result of climate policy, and overall physical consumption of these goods and services has fallen in response to the price increase. This implies some welfare loss associated with reduced consumption. However, GDP does not fall significantly, because the remaining consumption is multiplied by a higher price. In some cases (the electricity sector in particular), GDP is forecast to increase substantially as a result of increased consumption of a product (electricity). This would be associated with welfare losses, which are not accounted for using GDP.

Table 12 shows the projected impact of each policy simulation on the gross domestic product in Alberta's energy supply and demand sectors. Both the effect on total GDP as well as the effect on individual sub-sectors of the economy is shown.

¹⁹ Gross domestic product (GDP) is the standard measure used to calculate changes in a firm or sector's financial output for purposes of its contribution to sectoral or national income. GDP, also known as value added, is the sum of expenditures on capital, labour, and natural resources, the three "primary factors" of production, to produce a given good or service. The purpose of the GDP accounting method is to provide a consistent measure of national income, from an expenditure point of view, that eliminates the double counting of expenditure: once capital, labour and natural resources are counted, they then become an "intermediate input" to other processes, where they are not counted again. This system also accommodates the complexities of international production and consumption: it allows firms in Canada to import intermediate inputs and use them combined with capital and labour to create new goods, and in the process not over-represent Canadian "income content" accruable to this new product.

Throughout all the simulations, we forecast reductions in GDP from the crude oil extraction, petroleum refining, and transportation sectors and large increases in GDP from the electricity sector. At lower carbon charges, the net effect on GDP is slightly negative, while at higher carbon charges, the net effect on GDP is slightly positive for sectors covered by the CIMS model.

We explain the key dynamics underlying these results for the three most affected sectors:

- **Electricity generation sector** - Gross domestic product in the electricity sector rises substantially in all scenarios, for two main reasons. First, when a carbon charge is applied, energy-using sectors react by consuming relatively more

electricity (which is less GHG intense at the point of end use) and less fossil fuels (which are more GHG intense at the point of end use). In the more aggressive policy scenarios, this results in the electricity sector growing substantially more than in the reference case. Second, when the carbon charges are applied, the electricity sector invests heavily in new electricity generating technologies, including fossil fuel generation with carbon capture and storage and renewable electricity generation, in response to the carbon price. Both of these trends (increases in overall capacity and investments in emissions abatement) require significant new capital investments in the electricity sector. These increased capital expenditures in the electricity sector correspond to increased GDP.²⁰

- **Crude oil sector** – Gross domestic product in the crude oil sector is forecast to be reduced as a result of the implementation of carbon charges. In the modelling, we assumed that policies in Alberta would not affect the world price for crude oil. Likewise, we assumed that the total production of crude oil in Alberta would be unchanged as a result of Alberta’s policies (however the balance of exports and domestic consumption can change as a result of policies in the model).²¹ As a result, the gross output of the crude oil sector does not vary with the implementation of policy. Gross domestic product in the sector is equal to gross output less intermediate inputs (expenditures on fuel, and other intermediate goods). The modelling forecast significant increases in expenditures on intermediate inputs as a result of climate change policies because of fuel switching towards more expensive lower carbon fuels, equating to a reduction in GDP.

The reduction in GDP shown here would reduce rent (excess profit) in the industry. Because the royalties collected by government are related to economic rent in the industry, some of the loss in GDP shown here would correspond to a loss in government revenue.

- **Transport sector** – Gross domestic product in the transport sector is expected to fall as a result of implementation of carbon charges. Expenditure on personal and freight transportation falls, reducing GDP, mainly due to substitution away from more expensive low-efficiency vehicles like large pickup trucks and sport utility

²⁰ Gross domestic product is normally calculated by summing the expenditures in a sector on capital and labour. In the electricity sector, these expenditures increase as a result of policy as explained above, which increases GDP. GDP can also be calculated by summing the income in a sector. In the electricity sector, the income is equal to the price of electricity multiplied by the sales of electricity (minus the expenditures on intermediate inputs). When a policy is applied, both the price of electricity increases (because of increased abatement expenditures in the electricity sector) and the sales of electricity increase (because of fuel switching into electricity in the energy-consuming sectors). As a result, the GDP of the sector is increased.

²¹ While this assumption is unlikely to hold perfectly, world price of crude oil is forecast to remain quite high in the future, likely above the cost of producing crude oil in Alberta (this leads to economic rents). Increases in the cost of producing crude oil in Alberta would likely reduce excess rents, but not significantly reduce production.

FINAL REPORT

vehicles to less expensive high efficiency vehicles. Mode switching from single occupancy vehicles to high occupancy vehicles and to public transit also reduces expenditures in the transport sector.

The dynamics for all the simulations are generally similar, except stronger with the increase in GHG price. At higher carbon prices, the net gain in GDP is larger. This seemingly counter intuitive response is mainly due to the necessary capital expenditures in electricity production.

Finally, we reiterate that CIMS is not a full equilibrium model, with full modelling of labour and capital markets and structural shifts in non-energy intensive sectors. Our results show a significant increase in investments in the energy production and transformation sectors, but this increase may be accompanied by a reduction in investments in non-energy intensive sectors. While CIMS is an appropriate tool for analysis of the transforming effects of energy policy on the energy-using capital stock and general economy over time, full analysis of the effects of the potentially significant structural change we describe should be completed with a dedicated general equilibrium model.

Despite these caveats, the results do indicate that the overall effect of policies to reduce GHG emissions in Alberta is unlikely to be large, especially when compared to total GDP growth over in the future. Figure 28 shows projected GDP growth in Alberta in the reference case and in the four flat policy scenarios. Overall effects are projected to be nearly imperceptible over a 45-year period, once future growth in GDP is accounted for.

Figure 28: Alberta GDP in the alternative scenarios

Sector specific results

In addition to overall economic impact, we provide some analysis of economic impact of the policies at a sector level. Where possible, we provide historic data for context.

- **Residential** – Figure 29 shows the projected change in household expenditures on energy as a result of the implementation of carbon charges throughout the economy. Historical data are provided for context. The figure shows that real household energy expenditures are projected to decline slightly from today’s levels as a result of improved energy efficiency as well as declining real fuel prices. When GHG policies are implemented, household expenditures on energy are projected to increase by as much as 40 percent in the P4-F100 scenario. The increases are most severe in the near term, when the capital stock is relatively fixed. In the longer term, increases are much smaller as household stock becomes more efficient in response to higher energy prices.

Figure 29: Household expenditures on energy

Source: Historic data on energy consumption from NRCan’s “Comprehensive Energy Use Database”, 2007; historic data on electricity prices from Hydro-Québec’s “Comparison of Electricity Prices in Major North American Cities”; historic data on natural gas prices from CANSIM, Table 129-0003, “Sales of Natural Gas Monthly”.

- **Transportation** – Figure 30 shows projected changes in gasoline prices resulting from policy implementation. In the reference case, gasoline prices are expected to decline from current levels due to projected decreases in real crude oil price. In the P4-F100 scenario, gasoline price is expected to increase by around 40 percent compared to the reference case. Figure 31 shows annual vehicle fuel costs. Like gasoline prices, annual fuel costs are expected to decline from today’s high levels because of the projection of declining real crude oil prices. Increasing vehicle efficiency also contributes to a decline in annual vehicle expenditure on energy. When policies are applied, vehicle fuel costs increase significantly in the near term before moderating in the longer term, as the vehicle stock responds to higher fuel prices.

Figure 30: Gasoline price

Figure 31: Annual vehicle fuel cost

Source: Historic data on vehicle energy consumption from NRCan’s “Comprehensive Energy Use Database”, 2007; historic data on fuel prices from CANSIM, Table 329-0009, “Average Retail Prices for Gasoline and Fuel Oil by Urban Centres, Monthly”.

- **Electricity generation** – Figure 32 shows the forecast of residential electricity prices in Alberta. Prices are projected to increase gradually in the reference case, as new capital investments are required. Prices increase much more rapidly in the aggressive policy scenario, because significant abatement expenditures (primarily carbon capture and storage and renewable energy investments) occur in the electricity generation sector. These higher electricity prices cause some energy

efficiency and conservation investments in the residential sector, and in other electricity consuming sectors.

Figure 32: Electricity Prices (Residential)

Source: Historic data from Hydro-Québec’s “Comparison of Electricity Prices in Major North American Cities”.

- **Crude oil** – Figure 33 shows the increase in the cost of producing a barrel of oil from Alberta’s oil sands. The increase in costs range from less than \$1 per barrel to around \$5 per barrel in the most aggressive scenario. The costs of production increase most in the most aggressive scenario, due primarily to the costs associated with carbon capture and storage.

Figure 33: Increase in the cost of oil sands production

- **Natural gas** – Figure 34 shows the increase in cost of producing natural gas for several of the policy scenarios. The increase in costs is the result of carbon

capture and storage in natural gas processing plants, as well as some leak detention and repair programs.

Figure 34: Increase in the cost of natural gas production

- **Industrial sectors** – Table 13 shows the projected increase in the cost of production for the industrial sectors covered by CIMS. The biggest increases occur in the energy supply sectors, especially the electricity generation and crude oil sectors, which are particularly GHG-intensive.

Table 13: Projected increase in cost of production for energy supply and demand industries due to policy

Note: * We assumed a world price for crude oil that was unaffected by Alberta's GHG policies. Because crude oil represents the largest portion of expenditures in the petroleum refining sector, total cost of production remained relatively unchanged as a result of the policies, despite significant abatement expenditures.

Policy analyses

In addition to the carbon charges, we modelled the impact of several policy options on Alberta's GHG emissions. In particular, we modelled the following policies:

- **The carbon charge schedule specified for P5-Ea combined with a regulation that requires all large industrial facilities built after 2015 to capture and store their emissions (S1-EaCCS).** The CCS regulation covers electricity generation, petroleum refining, natural gas processing, and oil sands facilities and all large industrial manufacturing facilities.

- **The carbon capture and storage regulation simulated in S1-EaCCS applied on its own (S2-CCS).** This policy excludes the carbon charge from S1-EaCCS.
- **A change to the residential building code (S3-RBC).** We model a policy that requires new houses built in Alberta to be certified as Built Green™ Gold after 2010.
- **Construction of a new nuclear electricity generation plant (S4-NUC).** We model a scenario in which a 2,200 MW nuclear plant is commissioned to produce electricity for Alberta’s grid in 2020.
- **A vehicle emissions standard for new vehicles (S5-VES).** We model a policy where new passenger vehicles sold in Alberta must have an average greenhouse gas intensity below the levels specified in Table 14.

Table 14: Maximum average fleet GHG standard modelled in this report

| | 2011- 2015 | 2016- 2020 | 2021- onwards |
|--|---------------|---------------|------------------|
| Vehicle Emissions Standard (g CO ₂ /km) | 174 | 160 | 160 |

- **A revision to the commercial building code (S6-LEED).** We model a policy that requires all new commercial construction to meet LEED Gold™ standards after 2010.
- **Requirement for electricity generated from renewable sources (S7-REN).** We simulate a policy where 20% of electricity must be generated from renewable sources by 2020.
- **Policy Package (S8-PKG).** We model a policy package that includes several regulations targeted at different sectors of the economy. The policy package includes: 1) a requirement for all new large industrial facilities built after 2015 to capture and store their greenhouse gas emissions (S2-CCS); 2) a revision to residential building codes (S3-RBC); 3) the commissioning of 2,200 MW of nuclear power electricity generation in 2020 (S4-NUC); 4) the vehicle emissions standard for new vehicles (S5-VES); and 5) the commercial building code revision (S6-LEED).²²

Figure 35 illustrates the projection of Alberta’s GHG emissions in several of the policies, and Source: Historic data are from Environment Canada, 2007, “Greenhouse Gas Inventory”.

Table 15 shows the emissions reductions from the reference projection by sector.²³ S3-RBC, S4-NUC, S5-VES, S6-LEED, S7-REN produce modest reductions in GHG emissions, because the scope of the policies is limited to a few sectors – the residential sector in S3-RBC, the electricity generation sector in S4-NUC and S7-REN, the transportation sector in S5-VES, and the commercial sector in S6-LEED. S1-EaCCS, S2-

²² The electricity renewable standard has been excluded from the policy package to ease the modelling.

²³ S3-RBC, S6-LEED and S7-REN have been removed from Figure 35 because the difference between these simulations and S5-VES is small.

FINAL REPORT

CCS and S8-PKG, however, target a larger portion of the economy. The carbon capture and storage regulation (simulated in each of the policies) targets sectors which are responsible for the majority of Alberta’s emissions. S1-EaCCS adds a carbon charge to the CCS regulation, while S8-PKG adds additional regulations to cover emissions in sectors unaffected by the CCS regulation.

Figure 35: GHG emissions in each policy analysis

We present sector specific indicators on energy and greenhouse gas emissions for the regulatory policies below. In each figure, we show the indicators for different levels of carbon charges to enable a comparison between the effectiveness of the different policies. We also provide an estimate of the implicit carbon charge for several of the regulations. The implicit carbon charge is a measure of the level of carbon charge that would be required to induce similar abatement actions as the regulation. We only present select indicators in this section, but full results are available in the appendix.

Residential sector

Figure 36 and Figure 37 show the energy and greenhouse gas intensity of residential space heating in the S3-RBC scenario. As illustrated, the requirement for all new Alberta

FINAL REPORT

homes to meet the Built Green™ Gold standard after 2010 leads to similar declines in energy and greenhouse gas intensity as the flat \$30/tonne CO₂e carbon charge (P2-F30). One reason why the change in building codes does not attain greater declines in energy and greenhouse gas intensity is that the regulation only requires improvement of residential shells, whereas carbon charges induce GHG reductions throughout the entire house (e.g., furnaces, shells, lighting, appliances). Table 16 shows the implicit charge on greenhouse gas emissions from revising the residential building codes. The implicit GHG charges are relatively high because more efficient buildings only have a modest impact on greenhouse gas emissions.

Figure 36: Residential space heating energy intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Figure 37: Residential space heating direct GHG intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

Table 16: Implicit GHG charge for S3-RBC

|--|-------|-------|------|------|------|------|------|------|
| GHG Tax (2003\$/tonne CO ₂ e) | 1,770 | 1,330 | 880 | 430 | 210 | 200 | 190 | 170 |

Passenger transportation sector

Figure 38 and Figure 39 show the energy and greenhouse gas intensity of passenger vehicles in the S5-VES scenario.²⁴ At the beginning of the simulation, the vehicle emissions standard induces greater reductions in energy and greenhouse gas intensity than the carbon charges applied in the P5-Ea or P7-Ec scenarios. The standard requires a greater adoption of low emissions vehicles than occurs in P5-Ea or P7-E; therefore, the implicit greenhouse gas charge of the standard – illustrated in Table 17 – is greater than the carbon charge applied in P5-Ea or P7-Ec. Towards the end of the simulation, the carbon charge scenarios induce a greater adoption of low emissions vehicles than is required by the vehicle emissions standard.

²⁴ The intensity indicators for S8-PKG are not illustrated because they show a similar trend to S5-VES.

FINAL REPORT

Commercial sector

Figure 40 and Figure 41 show the energy and greenhouse gas intensity of commercial buildings in the S6-LEED scenario.²⁵ The requirement for new construction to meet LEED Gold™ standards after 2010 induces greater improvements in both energy and greenhouse gas intensity than the carbon charge simulated in P7-Ec. Unlike the revision to the residential building code, this standard induces energy efficiency improvements to most aspects of commercial buildings. The key actions that contribute to the decline in energy intensity are improvements to the outside shells, space heating systems and water heating systems. The implicit GHG charge at the beginning of the regulation, illustrated in Table 18, is much greater than the carbon charge simulated in P7-Ec. The regulation requires a greater improvement in energy efficiency than occurs in the P7-Ec scenario.

Figure 40: Commercial building energy intensity

Source: Historic data from NRCan’s “Comprehensive Energy Use Database”, 2007.

²⁵ The intensity indicators for S8-PKG are not illustrated because they show a similar trend to S6-LEED.

Figure 41: Commercial building direct GHG intensity

Table 18: Implicit GHG charge for S6-LEED

| | 2011- 2015 | 2016- 2020 | 2021- 2025 | 2026- 2030 | 2031- 2035 | 2036- 2040 | 2041- 2045 | 2046- 2050 |
|---|---------------|---------------|---------------|---------------|---------------|---------------|---------------|---------------|
| Implicit GHG charge (2003\$/tonne CO _{2e}) | 410 | 350 | 295 | 250 | 195 | 155 | 125 | 95 |

Electricity generation sector

Figure 42 shows the greenhouse gas intensity of electricity generation in the S1-EaCCS, S4-NUC and S7-REN scenarios.²⁶ The results show that both the construction of a 2,200 MW nuclear plant and the requirement for 20% of electricity generation to be from renewable sources by 2020 would reduce the emissions intensity of electricity generation to roughly the same level as a \$30/tonne CO_{2e} carbon charge by 2050. The construction of the nuclear plant yields a slightly greater reduction in greenhouse gas intensity because it leads to a greater installation of electric capacity from zero emissions sources. The scenarios that employ the carbon capture and storage regulation generally follow the intensity of the most aggressive carbon charge scenario (P7-Ec). The policies yield similar results because they all lead to a full application of carbon capture and storage – which is the main action to reduce emissions in each scenario. Source: Historic data from NRCan’s “Canada’s Energy Outlook”, 2007.

Table 19 shows the implicit GHG charge of requiring 20% of electric generation to be from renewables by 2020.

²⁶ The intensity indicators for S2-CCS and S8-PKG are not illustrated because they show a similar trend to S1-EaCCS.

Figure 42: Electricity generation GHG intensity

Table 19: Implicit GHG charge for S7-REN

| | 2011- 2015 | 2016- 2020 | 2021- onward |
|---|---------------|---------------|-----------------|
| Implicit GHG charge (2003\$/tonne CO ₂ e) | \$40 | \$40 | NA |

Crude oil sector

Figure 43 shows the greenhouse gas intensity of the oil sands in the S1-EaCCS and S2-CCS scenarios.²⁷ The decline in intensity in each scenario by 2050 is less than in the most aggressive carbon charge scenario (P7-Ec). While carbon capture and storage is a key action to reduce emissions in the sector, switching to low emissions fuels and energy efficiency actions contribute to significant emissions reductions in the P7-Ec scenario. S2-CCS, which does not apply a carbon charge, does not encourage these actions; and S1-EaCCS, which employs a less aggressive carbon charge than P7-Ec, does not encourage these actions to the same extent.

²⁷ The intensity indicator for S8-PKG is not illustrated because it shows a similar trend to S2-CCS.

Figure 43: Oil sands GHG intensity

Industrial Sectors

Figure 44 shows the greenhouse gas emissions in the industrial manufacturing sectors.²⁸ S1-EaCCS and S2-CCS lead to larger emissions reductions than the P7-Ec scenario because they encourage a greater application of carbon capture and storage. Carbon capture and storage is not fully applied in P7-Ec, because the carbon charges are not high enough at the beginning of the simulation to make CCS economically viable in all industrial sectors. The difference in the emissions trajectories between the S1-EaCCS and S2-CCS can be attributed to the carbon charge applied in S1-EaCCS, which encourages fuel switching and energy efficiency actions in addition to carbon capture and storage.

²⁸ The intensity indicator for S8-PKG is not illustrated because it shows a similar trend to S2-CCS.

Figure 44: Industrial GHG emissions

Figure 45 shows the wedge diagram for S1-EaCCS. Almost all reductions come from carbon capture and storage.

Figure 45: GHG reduction wedge diagram for S1-EaCCS

Deep reduction policy

The final purpose of this report is to assess the stringency of carbon charge required to attain a deep reduction in greenhouse gas emissions – 50% below 2005 levels by 2050. For this policy, we simulated a ceiling on carbon charges equal to \$300/tonne CO_{2e} (2003\$). Figure 46 shows the greenhouse gas projection, and Source: Historic data are from Environment Canada, 2007, “Greenhouse Gas Inventory”.

FINAL REPORT

Table 20 shows the carbon charge and the final sectoral emissions in the deep reduction policy (S9-DEEP). A carbon charge that rises to \$300/tonne CO₂e reduces emissions by 44% below 2005 levels, or 26% below 1990 levels. In other words, this policy still does not reduce emissions by 50% relative to 2005 levels by 2050. Source: Historic data are from Environment Canada, 2007, “Greenhouse Gas Inventory”.

Table 20 shows that in 2050 in the deep reduction scenario, 91% of the greenhouse gas emissions that remain are from four sectors –crude oil, natural gas, electricity generation, and transportation.

Figure 46: GHG emissions in the deep reduction scenario, excluding emissions from agrosystems and waste

Source: Historic data are from Environment Canada, 2007, “Greenhouse Gas Inventory”.

Table 20: Carbon charge and GHG emissions in the S9-DEEP scenario

| | 2020 | 2030 | 2040 | 2050 |
|---|-------|-------|-------|-------|
| Carbon Charge (2003\$/tonne CO₂e) | \$100 | \$300 | \$300 | \$300 |
| Alberta Total Emissions (Mt CO₂e) | 189 | 140 | 114 | 115 |
| Demand Sectors | | | | |
| Residential | 7 | 4 | 2 | 1 |
| Commercial | 5 | 4 | 2 | 1 |
| Transportation | 29 | 20 | 15 | 15 |
| Manufacturing Industry | 14 | 10 | 7 | 5 |
| Supply Sectors | | | | |
| Crude Oil | 68 | 59 | 54 | 61 |
| Natural Gas | 28 | 19 | 14 | 12 |
| Coal Mining | 1 | 1 | 1 | 1 |
| Electricity Generation | 30 | 19 | 16 | 18 |
| Petroleum Refining | 6 | 5 | 2 | 2 |
| Ethanol | 0 | 0 | 0 | 0 |

In each of these sectors, low emissions technologies have fully penetrated the market, however some emissions remain unabated for several reasons:

- **The expected economic growth from 2005 to 2050 makes a 50% reduction target difficult to attain.** Greenhouse gas emissions are expected to almost double between 2005 and 2050, if no additional policies are implemented. Therefore, greenhouse gas intensity would have to decline substantially to maintain emissions in 2050 at their 2005 levels. Greenhouse gas intensity would have to decline even more dramatically to attain a deep (50%) reduction in emissions.
- **Carbon capture and storage only reduces greenhouse gas emissions by 85% in comparison to an equivalent technology.** In the crude oil, natural gas, and electricity sectors, carbon capture and storage becomes widely adopted in the deep reduction scenario; however, these technologies still emit a small amount of greenhouse gas emissions. A large portion of the emissions that remain at the end of S9-DEEP are unabated emissions from technologies that employ carbon capture and storage. It is possible that the capture rate from carbon capture technologies will improve beyond the 85% that is modelled in CIMS, which would further reduce emissions.
- **There may be technical limits to abatement in the crude oil and natural gas sectors.** While there are many opportunities for abating greenhouse gas emissions in these sectors, some emissions may lack abatement options. For example, the oil sands exposed during mining operations emit a large amount of methane emissions, for which we do not foresee an abatement option. Therefore, we assume that a minimum amount of emissions will occur as long as there is activity in the sector. It is possible that new technologies or processes will be developed to reduce these emissions, which are not currently included in the CIMS model.
- **There may be technical limits to abatement in the transportation sector.** In 2050, CIMS simulates a relatively full penetration of low emissions technologies in the transportation sector. For example, hybrid and plug-in hybrid vehicles account for the majority of the stock of passenger vehicles in 2050. However, many of these technologies still produce a small amount of emissions (hybrid vehicles still consume some fossil fuel).
- **CIMS may lack abatement options that emerge in response to a strong carbon charge.** CIMS has a detailed representation of individual technologies, but it is limited to technologies that are presently available, or technologies that currently exist and may be commercialized in the foreseeable future (e.g., carbon capture and storage or electric cars). It does not include technologies that may be invented in response to a policy. For example, carbon capture and storage as currently planned reduces emissions by approximately 85%, but it is possible that methods to improve capture efficiency could be developed if a strong signal is

FINAL REPORT

sent to emitters. Additionally, innovative ways to capture or prevent the methane emissions from exposed oil sands may emerge if a strong policy were levied; producers could also decide to only extract bitumen using in-situ methods, with much lower fugitive emissions.

Figure 47 shows the wedge diagram for the deep reduction policy. Carbon capture and storage plays a dominant role in reducing emissions, while fuel switching and energy efficiency measures account for approximately 25% of the total reductions.

Figure 47: GHG reduction wedge diagram for S9-DEEP

Table 21 shows the projected impact of S9-DEEP on the gross domestic product of Alberta's energy supply and demand sectors.

Table 21: Estimated effect of S9-DEEP on gross domestic product in sectors covered by CIMS (millions of \$2003)

| | <i>S9-DEEP</i> | |
|---------------------------|----------------|-------------|
| | <i>2025</i> | <i>2050</i> |
| Total GDP Change | 988 | 6,585 |
| Percent GDP Change | 0.40% | 1.71% |
| Demand Sectors | | |
| Residential | 116 | 39 |
| Commercial | -21 | 112 |
| Transportation | -2,435 | -1,382 |
| Manufacturing Industry | 69 | 103 |
| Supply Sectors | | |
| Crude Oil | -1,879 | -6,906 |
| Natural Gas | -80 | 66 |
| Coal Mining | -2 | -4 |
| Electricity Generation | 5,328 | 14,444 |
| Petroleum Refining | -127 | -313 |
| Ethanol | 20 | 425 |

The economic impacts of S9-DEEP are generally similar to the impacts of the other carbon charges, except the impacts are stronger. Again we reiterate that CIMS is not a full equilibrium model, with full modelling of labour and capital markets and structural shifts in non-energy intensive sectors. In order to accurately estimate the impact on GDP, it would be necessary to account for the policy's effects on all markets and sectors of the economy.

Appendix A – CIMS model description

Introduction to the CIMS model

CIMS has a detailed representation of technologies that produce goods and services throughout the economy and attempts to simulate capital stock turnover and choice between these technologies realistically. It also includes a representation of equilibrium feedbacks, such that supply and demand for energy intensive goods and services adjusts to reflect policy.

CIMS simulations reflect the energy, economic and physical output, GHG emissions, and CAC emissions from its sub-models as shown in Table 22. CIMS does not include agricultural land-use, the waste sector, solvent, or hydrofluorocarbon (HFC) emissions. As a result, the GHG emissions in CIMS represent only about 80% of the Canadian total (about 82% of the Alberta total). CIMS covers nearly all CAC emissions in Canada except those from open sources (like forest fires, soils, and dust from roads).

Table 22: Sector Sub-models in CIMS

| Sector | BC | Alberta | Sask. | Manitoba | Ontario | Quebec | Atlantic |
|---------------------------------|----|---------|-------|----------|---------|--------|----------|
| Residential | | | | | | | |
| Commercial/Institutional | | | | | | | |
| Transportation | | | | | | | |

| Iron and Steel | | | | | | | |
| Non-Ferrous Metal Smelting* | | | | | | | |
| Metals and Mineral Mining | | | | | | | |
| Other Manufacturing | | | | | | | |
| Pulp and Paper | | | | | | | |
| Energy Supply | | | | | | | |
| Coal Mining | | | | | | | |
| Electricity Generation | | | | | | | |
| Natural Gas Extraction | | | | | | | |
| Petroleum Crude Extraction | | | | | | | |
| Petroleum Refining | | | | | | | |

* Metal smelting includes Aluminium.

Model structure and simulation of capital stock turnover

As a technology vintage model, CIMS tracks the evolution of capital stocks over time through retirements, retrofits, and new purchases, in which consumers and businesses make sequential acquisitions with limited foresight about the future. This is particularly important for understanding the implications of alternative time paths for emissions reductions. The model calculates energy costs (and emissions) for each energy service in the economy, such as heated commercial floor space or person kilometres travelled. In each time period, capital stocks are retired according to an age-dependent function

FINAL REPORT

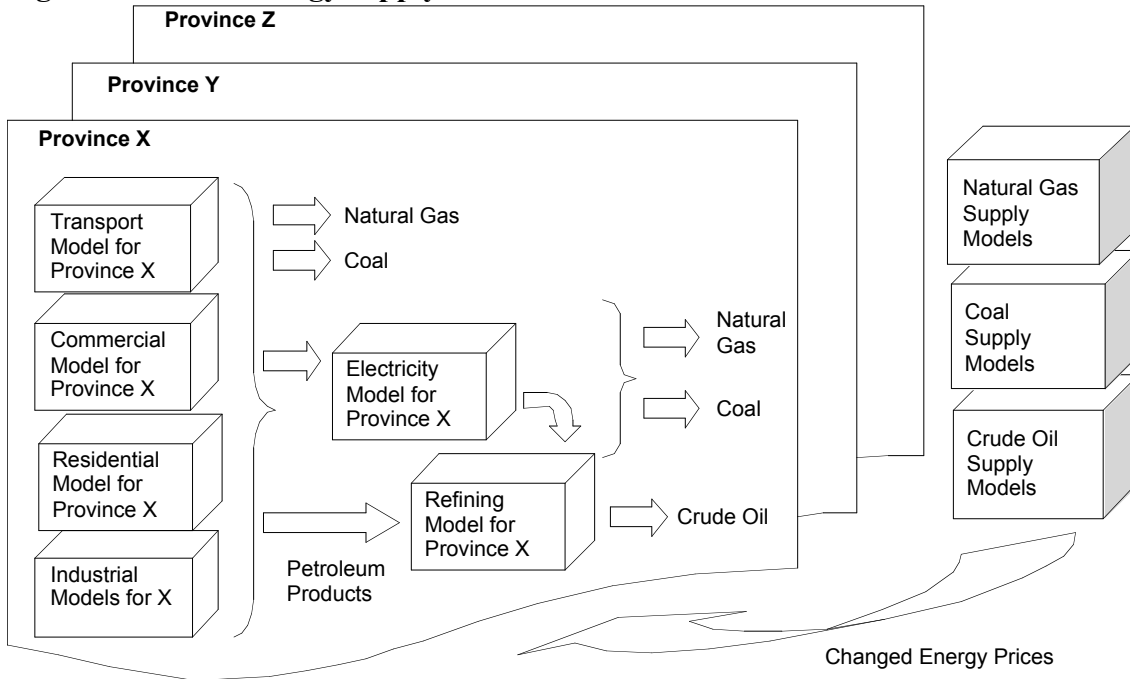

(although retrofit of un-retired stocks is possible if warranted by changing economic conditions), and demand for new stocks grows or declines depending on the initial exogenous forecast of economic output, and then the subsequent interplay of energy supply-demand with the macroeconomic module. A model simulation iterates between energy supply-demand and the macroeconomic module until energy price changes fall below a threshold value, and repeats this convergence procedure in each subsequent five-year period of a complete run.

CIMS simulates the competition of technologies at each energy service node in the economy based on a comparison of their life cycle cost (LCC) and some technology-specific controls, such as a maximum market share limit in the cases where a technology is constrained by physical, technical or regulatory means from capturing all of a market. Instead of basing its simulation of technology choices only on financial costs and social discount rates, CIMS applies a definition of LCC that differs from that of bottom-up analysis by including intangible costs that reflect consumer and business preferences and the implicit discount rates revealed by real-world technology acquisition behaviour.

Equilibrium feedbacks in CIMS

CIMS is an integrated, energy-economy equilibrium model that simulates the interaction of energy supply-demand and the macroeconomic performance of key sectors of the economy, including trade effects. Unlike most computable general equilibrium models, however, the current version of CIMS does not equilibrate government budgets and the markets for employment and investment. Also, its representation of the economy's inputs and outputs is skewed toward energy supply, energy intensive industries, and key energy end-uses in the residential, commercial/institutional and transportation sectors.

CIMS estimates the effect of a policy by comparing a business-as-usual forecast to one where the policy is added to the simulation. The model solves for the policy effect in two phases in each run period. In the first phase, an energy policy (e.g., ranging from a national emissions price to a technology specific constraint or subsidy, or some combination thereof) is first applied to the final goods and services production side of the economy, where goods and services producers and consumers choose capital stocks based on CIMS' technological choice functions. Based on this initial run, the model then calculates the demand for electricity, refined petroleum products and primary energy commodities, and calculates their cost of production. If the price of any of these commodities has changed by a threshold amount from the business-as-usual case, then supply and demand are considered to be out of equilibrium, and the model is re-run based on prices calculated from the new costs of production. The model will re-run until a new equilibrium set of energy prices and demands is reached. Figure 48 provides a schematic of this process. For this project, while the quantities produced of all energy commodities were set endogenously using demand and supply balancing, endogenous pricing was used only for electricity and refined petroleum products; natural gas, crude oil and coal prices remained at exogenously forecast levels (described later in this section), since Canada is assumed to be a price-taker for these fuels.

Figure 48: CIMS energy supply and demand flow model

In the second phase, once a new set of energy prices and demands under policy has been found, the model measures how the cost of producing traded goods and services has changed given the new energy prices and other effects of the policy. For internationally traded goods, such as lumber and passenger vehicles, CIMS adjusts demand using price elasticities that provide a long-run demand response that blends domestic and international demand for these goods (the “Armington” specification).²⁹ Freight transportation is driven by changes in the combined value added of the industrial sectors, while personal transportation is adjusted using a personal kilometres-travelled elasticity (-0.02). Residential and commercial floor space is adjusted by a sequential substitution of home energy consumption vs. other goods (0.5), consumption vs. savings (1.29) and goods vs. leisure (0.82). If demand for any good or service has shifted more than a threshold amount, supply and demand are considered to be out of balance and the model re-runs using these new demands. The model continues re-running until both energy and goods and services supply and demand come into balance, and repeats this balancing procedure in each subsequent five-year period of a complete run.

Empirical basis of parameter values

Technical and market literature provide the conventional bottom-up data on the costs and energy efficiency of new technologies. Because there are few detailed surveys of the annual energy consumption of the individual capital stocks tracked by the model (especially smaller units), these must be estimated from surveys at different levels of

²⁹ CIMS’ Armington elasticities are econometrically estimated from 1960-1990 data. If price changes fall outside of these historic ranges, the elasticities offer less certainty.

FINAL REPORT

technological detail and by calibrating the model's simulated energy consumption to real-world aggregate data for a base year.

Fuel-based GHGs emissions are calculated directly from CIMS' estimates of fuel consumption and the GHG coefficient of the fuel type. Process-based GHGs emissions are estimated based on technological performance or chemical stoichiometric proportions. CIMS tracks the emissions of all types of GHGs, and reports these emissions in terms of carbon dioxide equivalents.³⁰

Both process-based and fuel-based CAC emissions are estimated in CIMS. Emissions factors come from the US Environmental Protection Agency's FIRE 6.23 and AP-42 databases, the MOBIL 6 database, calculations based on Canada's National Pollutant Release Inventory, emissions data from Transport Canada, and the California Air Resources Board.

Estimation of behavioural parameters is through a combination of literature review, judgment, and meta-analysis, supplemented with the use of discrete choice surveys for estimating models whose parameters can be transposed into behavioural parameters in CIMS.

Simulating endogenous technological change with CIMS

CIMS includes two functions for simulating endogenous change in individual technologies' characteristics in response to policy: a declining capital cost function and a declining intangible cost function. The declining capital cost function links a technology's financial cost in future periods to its cumulative production, reflecting economies-of-learning and scale (e.g., the observed decline in the cost of wind turbines as their global cumulative production has risen). The declining capital cost function is composed of two additive components: one that captures Canadian cumulative production and one that captures global cumulative production. The declining intangible cost function links the intangible costs of a technology in a given period with its market share in the previous period, reflecting improved availability of information and decreased perceptions of risk as new technologies become increasingly integrated into the wider economy (e.g., the "champion effect" in markets for new technologies); if a popular and well respected community member adopts a new technology, the rest of the community becomes more likely to adopt the technology.

³⁰ CIMS uses the 2001 100-year global warming potential estimates from Intergovernmental Panel on Climate Change, 2001, "Climate Change 2001: The Scientific Basis", Cambridge, UK, Cambridge University Press.

| Freight Energy Intensity (MJ/tkt) | 0.85 | 0.50 | 0.41 | 0.45 |
| Freight Emissions Intensity (kg CO ₂ e/tkt) | 0.06 | 0.03 | 0.01 | 0.01 |
| Increase in Annual Vehicle Fuel Costs (2003\$/vehicle) ¹ | \$243 | \$650 | \$405 | \$261 |
| Increase in Gasoline Price (2003¢/L) ¹ | 25.0 | 74.9 | 74.9 | 74.9 |
| Electricity Generation | | | | |
| Energy Intensity (GJ Fuel/GJ Electricity) | 2.51 | 2.33 | 2.36 | 2.51 |
| GHG Intensity (t CO ₂ e/GJ Electricity) | 0.10 | 0.04 | 0.02 | 0.02 |
| Upstream Oil and Gas | | | | |
| Oil Sands Energy Intensity (GJ/m ³ crude) | 7.83 | 7.61 | 7.30 | 7.19 |
| Oil Sands GHG Intensity (t CO ₂ e/m ³ crude) | 0.32 | 0.25 | 0.20 | 0.19 |
| Increase in Cost of Oil Sands Production (2003\$/barrel) ¹ | 3.39 | 3.68 | 4.34 | 4.68 |
| Increase in Cost of Gas Production (2003\$/GJ) ¹ | 0.16 | 0.28 | 0.33 | 0.37 |

¹ Represents an increase over the reference case.
